An ultrastructural and viscoelastic study of the hypercoagulable state of breast cancer patients and the implications for the disease

Janette Bester and Julien Nunes Concalves
University of Pretoria, School of Medicine, RSA

Statement of the Problem: Breast cancer patients are at an increased risk for thrombotic events such as deep vein thrombosis (DVT) and venous thromboembolism (VTE), drastically affecting survival and quality life of patients post treatment. It has been proposed that this increased risk is caused by cancer associated inflammation induced hyper coagulation, a key factor involved in thrombus formation.

Methodology & Theoretical Orientation: This study utilized microscopy and rheological techniques to examine coagulation components during clot formation, in order to obtain a better understanding of how changes to these components may increase thrombus formation and thus the risk of thrombotic events. Whole blood from treatment naïve breast cancer patients were compared to whole blood from healthy controls. Routine clinical tests were used to obtain an overall clinical picture of each participant. Scanning electron microscopy was used to study the fine ultrastructure of the red blood cells and platelets. Thromboelastography (TEG) was used to study the changes in clot dynamics during coagulation.

Findings: SEM showed platelets to be activated as well as a presence of spontaneous fibrin fibre formation. Also, red blood cells from the patient group showed more irregular surface membranes, increased agglutination and eryptosis when compared to healthy controls. Results from the TEG showed that clots form faster in breast cancer patients with increased strength and rigidity, thus revealing the hypercoagulable nature of whole blood in this patient group. The results in this study have revealed the marked differences in coagulation and associated blood components between healthy controls and treatment naïve breast cancer patients.

Conclusion & Significance: They provide a greater understanding of clot formation dynamics and have shown that even in a small sample size, breast cancer patients are at an increased risk of thrombotic events, traceable through rheological techniques. This justifies further investigation into the utilization of these techniques in a clinical, point of care setting, in order to increase the chance of survival and quality of life for these patient's post-treatment.

Figure: Scanning electron images of whole blood. A: Healthy control group images showing normal red blood cells B: Breast cancer group images showing abnormal deformed red blood cells. Scale: 1µm

Biography

Janette Bester research mainly focusses on vascular complications, specifically hemorheology in chronic inflammatory diseases such as type 2 diabetes, breast cancer and prostate cancer patients. She has been establishing her research group as well as her research focus since, 2015. She uses novel techniques that distinguish her from most of the research in her field. Her goal with her research is to improve tissue perfusion to improve wound healing as well as quality of life in patients with vascular complications as well as to determine the thrombotic risk in a specific patient population.
