### Abstract

**Objective:** To report for the first time critically ill patients with disseminated intravascular coagulation (DIC) in whom the infusion of 25% albumin solution produces remarkable elevations in plasma antithrombin III (AT) activities after administration of AT agents.

**Design:** A prospective observational study.

**Interventions:** 1) Plasma AT activities were serially measured in DIC patients after AT administration, enable us to analyze their pharmacokinetics; 2) Comparisons of AT activities between two groups of receiving AT agent with or without the infusion of 25% albumin solution; 3) *in vitro* examinations were conducted to define whether albumin application itself would influence directly an AT measurement system using samples already determined the levels of AT activities.

**Methods and main results:** Twenty consecutive critical patients with DIC were divided into two groups: groups receiving AT agents of 1500 units with (N=11) and without (N=9) the application of 25% albumin solutions. Patients treated with albumin solutions after AT agents showed remarkable elevations in AT peak and trough activities, whereas patients receiving the same dose of the AT agents without albumin co-administration did not maintain its trough activity. Pharmacokinetic analyses revealed that patients had shortened the distribution half-life time of AT, suggesting enhanced vascular permeability. The levels of AT activities in patients treated with both albumin and AT agents (N=11) were significantly higher than those without albumin administration (N=9, p=0.01). Furthermore, *in vitro* albumin applications to the AT measurement system did not effect on its values in the samples.

**Conclusion:** This is the first report indicating that 25% albumin administration could elevate and sustain AT activities, even when a limited AT dose was administered to DIC patients with increased vascular permeability. This may be due to a certain binding effect of albumin, which needs to be defined in the future.

### Introduction

Antithrombin III (AT) activity beyond its physiological range may obtain anti-coagulatory and anti-inflammatory effects in septic patients with DIC [1]. A large amount of the agent (6,000 units for four days) could achieve such goal, but there was a bleeding tendency in such patients with severe platelet depletion [2]. It would be worthwhile if we could maintain effectively AT levels using a certain limited dose of AT agents. We found critical DIC patients in whom 25% albumin infusion elevated plasma AT activities remarkably after AT agent administration at a dose of 1500 units for three days. After that, we examined retrospectively the effects of 25% albumin solution after AT administrations on plasma AT activities in critically ill patients with DIC. Furthermore, pharmacokinetic parameters were estimated in such patients.

### Subjects and Methods

**General:** Twenty consecutive critical patients diagnosed as DIC were reviewed in this study. Patients were divided into two groups: groups receiving AT agents with (N=11) or without (N=9) 25% albumin solutions (Japan Blood Product Organization: JBPO; CSL Behring Corporation). Demographic data of the patients are shown in the

Table 1. AT agents were administered at 1500 units once per day for three days. Such doses were applied when plasma AT activity decreased below 70%. This AT dose was used for DIC treatment, which adhered to the recommendation of a government-run Health Care Insurance System in Japan [3]. No co-administration of anti-coagulants such as heparin, gabexate mesilate or nafamostat mesilate was done in any of the patients. Other treatments such as antibiotic administrations, fluid infusion, cardiovascular and respiratory supports were decided by each physician in charge. DIC was diagnosed based on the criteria proposed by the Research Committee on DIC of the Japanese Association for

Acute Medicine criteria [4]. Sepsis diagnosis was made according to established criteria [5]. This retrospective study was approved to publish by the Ethics Committee of Ehime University Hospital.

**Measurement for AT activity, AT antigen and albumin:** Plasma AT antigen and activity were measured by a latex agglutination method (NS auto-AT kit, Naska Corp., Tokyo, Japan; Bio-majesty analyzer, Nihon Denshi Corp. Japan) and a synthesized substrate assay (Test-team S kit for AT, Dai-Ichi Kagaku Corp., Tokyo, Japan; CA 7000 analyzer, Sysmex, Tokyo, Japan), respectively. Serum albumin levels were determined by the Bromocresol Green method, followed by reflection spectrometry (Auto-analyzer 7450, Hitachi, Japan). The normal range for each test is as follows: AT antigen, 19-30 mg/dl; AT activity, 70-110%; albumin, 3.5-4.5 g/dl, respectively.

**PK analysis for AT:** A two-compartment model was used for this study. In all patients, AT activities were measured from plasma samples taken at the pre-infusion (trough level), 30, 60, 120, and 180 minutes after the initiation of the agent. Exceptionally in a case depicted in Figure 1B, additional plasma samples were obtained twelve hours after AT administration. AT of 1500 units was infused for 60 minutes. Such multiple blood samplings had been done for defining PK profile in critical patients with DIC. MULTI [6], a non-linear least square method

program, was used with an NEC PC-9801 computer (Tokyo, Japan) for the analyses. The Unit/Antigen Ratio (IU/mg) of AT agent used in this study was  $6.3 \pm 0.1$  [7]. AT concentrations in all patients here were assessed through activity (%) as well as antigen concentrations (mg/dl). AT activities and antigen levels were correlated well ( $r^2=0.92$ ,  $p=0.0001$ ). Therefore, subsequent PK evaluations were done by AT activity results. These procedures were reported in detailed in previous papers [8,9]. As a control, we cited data from a previous paper regarding AT pharmacokinetic analysis in patients with congenital AT deficiency [10]. These patients had normal PK profiles of a steady state.

**Ex vivo examination for influence on AT measurement system by albumin application in plasma samples:** We used sixteen samples in which AT activities had been already measured to clarify whether ex vivo 25% albumin application (1/10 volume of each sample volume) affected the AT activity values in each. We examined a correlation of calculated values with direct measured values when each sample was diluted to a 9/10 concentration. As shown in Figure 2B, a good

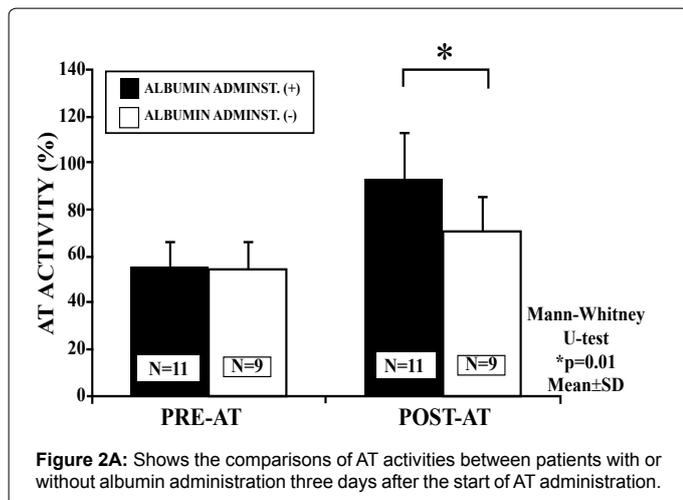

Figure 2A: Shows the comparisons of AT activities between patients with or without albumin administration three days after the start of AT administration.

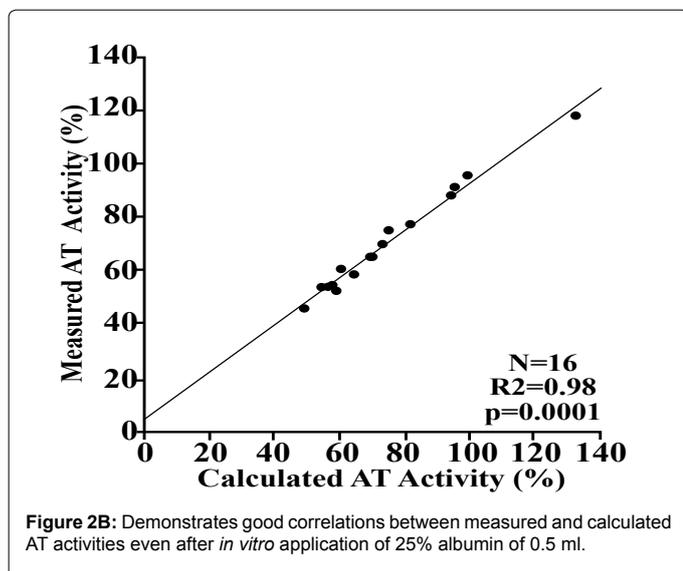

Figure 2B: Demonstrates good correlations between measured and calculated AT activities even after *in vitro* application of 25% albumin of 0.5 ml.

correlation with the two parameters ( $N=16$ ,  $r^2=0.98$ ,  $p=0.0001$ ) was obtained, suggesting that albumin application itself did not significantly affect AT activity values in the measurement system.

## Results

Figure 1A is a typical course of a patient receiving only AT agents of 1500 units. The patient showed transient increases in AT activities after AT administration, which were followed by a return to near the pre-administration levels. In contrast, as demonstrated in Figure 1B, a patient who was administered AT agents of 1500 units with 25% albumin solution showed remarkable elevations in AT activities.

As depicted in Figure 2A, patients receiving AT agents with 25% albumin solution had a higher level of plasma AT activity than those without albumin administrations three days after the start of AT agent.

Figure 2B demonstrates good correlations between measured and calculated AT activities in sixteen samples.

## Discussion

### Potential benefits of high concentration albumin on AT activity elevation after AT agent administration

It would be worth using a certain limited dose of AT agent if we could maintain AT trough levels effectively, since the large amount of the agent should be costly and have a bleeding tendency. There is a previous study for AT agent in septic patients [1], in which two methods were tested: 1) a 6000 unit bolus injection of AT agent followed by an intermittent 1000 unit administration every four hours for four days, 2) the same first bolus infusion followed by continuous AT administration at 250 units/hour for the same period. Both methods sustained AT activities around 150% even from thirty minutes after the treatment, lasting until the end of study. It is not surprising that such a large dose of AT maintained high levels of AT activity. We have presented here for the first time that in patients with DIC, co-administration of high concentration albumin elevated and sustained AT trough activity around 100% after AT agent delivered in a dose of just 1500 units once a day for three days. Furthermore, the pharmacokinetic profiles of these patients revealed heightened vascular permeability. Thus, future study is warranted to test the hypothesis that in DIC patients with enhanced vascular permeability, a limited dose of AT improves AT activity when 25% albumin solutions are co-administered.

### Accuracy of AT activity measurement after 25% albumin application

We used plasma samples in which AT activities had been already determined to clarify whether *in vitro* 25% albumin application (1/10 volume of each sample volume) affected AT activity values in each sample. We examined a correlation of calculated values with measured values when each sample was diluted to a 9/10 concentration. As shown in Figure 2B, a good correlation with the two parameters ( $N=16$ ,  $r^2=0.98$ ,  $p=0.0001$ ) was obtained, suggesting that albumin application itself did not significantly affect AT activity values in the measurement system. Thus, it appears that the remarkable elevation in AT activity after AT agent with co-administration of 25% albumin is a biological finding.

### Possible mechanisms for AT activity elevation after 25% albumin administration

Numerous biological effects of high concentration albumin have been reported including its binding capacity to other molecules [11] and attenuation of increased vascular permeability [12]. In this report, we have presented that patients had heightened vascular permeability and augmented distribution volume. Furthermore, we have suggested in a previous paper that reductions in albumin as well as AT in patients with DIC are due mainly to capillary leakage [8]. Therefore, it is likely that the two above-mentioned albumin mechanisms could be a cause for the remarkable elevation presented in this paper in AT activity after administration of AT agent with albumin. However, since the changes in AT activity after albumin infusion occurred so rapidly, it can be speculated that albumin binding capacity rather than attenuation of vascular permeability is more closely related to the present findings. Therefore, we need to test such a hypothesis in the future.
