Abstract
Aortic stenosis is one of the most common forms of acquired valvular heart disease in older patient population. Recent pre-clinical, observational, and clinical studies have shown that several biomarkers might have a powerful predictive utility in patients with asymptomatic and symptomatic aortic stenosis as well as predictors of clinical outcomes after aortic valve implantation (Table 1). Unfortunately, no any head-to-head studies to compare cardiac biomarkers measurement and echocardiography and yet this is a powerful limitation for scientifically discussion around advantages of cardiac biomarkers in older aortic stenosis individuals, whereas there are perspectives of continuing investigations toward this direction.

Keywords: Aortic stenosis; Older patients; Biomarkers; Mortality; Prediction

Introduction
Aortic stenosis is one of the most common forms of acquired valvular heart disease in older patient population [1]. It is well known that clinical signs and symptoms of aortic stenosis, i.e., angina, exertional dyspnea, syncope, and chronic heart failure (HF), might strongly predict a high likelihood of mortality in short-term perspective [2,3]. In contrast, asymptomatic patients with severe aortic stenosis have better clinical outcomes, but prognostications among these individuals remain very difficult yet [4,5]. Once a determination is made that cardiac surgery will be considered, the patient should be evaluated for the risk of a cardiovascular (CV) complications. Obviously, cardiac functional status should be determined. To our knowledge, whether integrated ventricular, vascular, and valvular components in asymptomatic patients with moderate to severe aortic stenosis could have utility at risk stratification and in enrollment for aortic valve replacement is still not clear [6]. Theoretically, a single symptom-limited exercise stress test could offer more precise risk stratification of these patients and increased a predictive power of echocardiographic parameters [7,8]. In symptomatic patients with aortic stenosis, however, an assessment of hemodynamic obstruction defined by two- and three-dimensional echocardiographic and Doppler indexes might be suboptimal due to technical difficulties and poor correlation with symptoms [9]. Other important diagnostic tools include cardiac catheterization, treadmill stress testing, and dobutamine stress echocardiography, although their use is limited to specific patient populations [10]. Therefore, aortic valve calcification may be an independent risk factor for adverse clinical outcome in persons with asymptomatic and symptomatic aortic stenosis [11,12]. In this context clinical implementation of cardiac biomarker measurement for risk stratification among patients with aortic stenosis depending lower and higher CV risk would appear to be attractive. Nevertheless, it is not clear how could be combined risk prediction by echocardiography / other cardiac functional status diagnostic tool with cardiac biomarkers’ measurement. The aim of the short communication is summary knowledge regarding clinical perspectives in use of biological markers for risk stratification in the patients with aortic stenosis.

Biomarkers and aortic stenosis
As well known a prominent attribute of aortic stenosis is calcification of valve leaflets / aortic root, accelerated atherothrombosis, endothelial dysfunction, and low-grading inflammation. All these factors might contribute in angina, syncope, HF, and worsening of kidney function. Recent pre-clinical, observational, and clinical studies have shown that several biomarkers might have a powerful predictive utility in patients with asymptomatic and symptomatic aortic stenosis, as well as predictors of clinical outcomes after aortic valve implantation (Table 1). Unfortunately, no any head-to-head studies to compare cardiac biomarkers measurement and echocardiography and yet this is a powerful limitation for scientifically discussion around advantages of cardiac biomarkers in older aortic stenosis individuals, whereas there are perspectives of continuing investigations toward this direction. 

Brain natriuretic peptides
Natriuretic peptides (NPs) are recognized as markers of biomechanical cardiac stress that are secreted resulting in stretching cardiac wall / volume overload and they have demonstrated high diagnostic and predictive value for heart failure (HF) [13]. Recent clinical studies have shown that brain natriuretic peptide (BNP) and NT-proBNP levels are elevated in patients with aortic stenosis and decrease acutely after replacement of the stenotic valve including transcatheter aortic valve implantation (TAVI) [14]. Moreover, high pre-intervention serum BNP level independently predicted two-year cardiovascular outcomes after TAVI [14]. Indeed, authors reported that patients with high baseline BNP (higher tertile ≥ 591 pg/ml) had increased risk of all-cause mortality (adjusted hazard ratio 3.16, 95% confidence interval 1.84 to 5.42; p<0.001) and cardiovascular death at 2 years (adjusted hazard ratio 3.37, 95% confidence interval 1.78 to 6.39; p<0.001). Outcomes were most unfavorable in patients with persistently high BNP before and after intervention. Comparing the two biomarkers, NT-pro-BNP levels measured after TAVI showed the highest prognostic discrimination for 2-year mortality (area under the curve 0.75; p<0.01). Therefore, BNP and NT-proBNP levels have shown a correlation with outcomes in studies of aortic valve surgery

MicroRNAs (miRNA) are short non-coding RNAs that play a pivotal role in posttranscriptional regulation of target cell function. It has been found that miRNA-21-5p has elevated in patients with aortic stenosis without presentation of presence of coexisting coronary artery disease (CAD). In contrast, increased serum concentrations of miR-22-3p, miR-24-3p, miR-382-5p, and miR-451a were not detected. Despite miRNA-21-5p appear to be promised as biomarker of aortic stenosis, there are more evidences regarding clinically significance of miRNA signature refinement in prediction of aortic stenosis evolution [18].

Growth differentiation factor 15

Growth Differentiation Factor-15 (GDF-15) is secreted cytokine belonging to the TGF-β super-family that highly expressed in states of inflammatory stress. GDF-15 may play a critical role in the atherosclerotic process in various vascular beds, starting from endothelial dysfunction and counting all stages of plaque development, as well as in ectopic calcification and aortic stenosis [19]. Elevated GDF-15 was found in older patients with asymptomatic and symptomatic moderate-to-severe aortic stenosis. Recent clinical study revealed that GDF-15 was superior to NT-proBNP for TAVI risk stratification and provided additional prognostic information in aortic stenosis [20].

High-sensitivity soluble toll-like receptor-2

Soluble ST2 (sST2) is receptor for cytokine IL-33 that is up-regulated in response to myocardial stress and exerts cardio-protective actions in the myocardium by reducing fibrosis, hypertrophy and enhancing in response to myocardial stress and exerts cardio-protective actions [21]. Current clinical guidelines have been recommended a measurement of sST2 as useful biomarker for death or cardiac troponins [21]. Current clinical guidelines have been recommended a measurement of sST2 as useful biomarker for death or cardiac troponins [21].

Fibroblast growth factor-23

Fibroblast Growth Factor-23 (FGF-23) is phosphate-regulating 251-amino-acid protein secreted by osteocytes and regulates mineral metabolism and inflammatory response [27]. FGF-23 increases urinary phosphorus excretion by decreasing phosphorus re-absorption in the proximal tubule of nephron and inhibits 1,25-dihydroxyvitamin D synthesis, resulting in decreased dietary phosphorus absorption from the gastrointestinal tract. Therefore, biological role of FGF-23 affects ectopic calcification and heart failure and stable coronary artery disease. Therefore, mild elevated level of highly-sensitivity circulating cardiac troponins was found in untreated symptomatic aortic stenosis patients independently of traditional CV risk factors unless myocardial infarction. Moreover, high sensitive troponin T can be useful biomarkers to predict the occurrence of heart failure, atrial fibrillation, and death after aortic valve replacement surgery [26]. However, the predictive role of hs-cTnT in older patients with asymptomatic aortic stenosis is not clear yet.

Table 1: Perspective cardiac biomarkers for risk stratification in aortic stenosis patients.
leading to increased GFG-23 are not fully investigated. There are evidences that hypoxia and ischemia through unknown mechanisms may induce GFG-23 over production. It is suggested that GFG-23 may affect on target cells directly and through GFG-23-related effects. In animal models GFG-23 directly stimulate left ventricular hypertrophy by activating hypertrophic gene programs, promoting cardiomyocyte growth, and stimulating the release of natriuretic peptides [30,31]. GFG-23 also inhibits 1,25-dihydroxyvitamin D via effects on CYP27B1 and CYP24A1 enzymes, stimulates the renin-angiotensin system via binding with Klotho, which is a key cofactor for GFG-23 [29]. Although elevated intact GFG-23 was found in aortic stenosis patients with heart failure, the role of this biomarker in risk stratification of the patients is not fully understood. Probably, GFG-23 could help to stratify the older patients with aortic stenosis beyond classical CV risk factors and individualize the medical care.

Galectin-3

Galectin-3 is a soluble beta galactoside-binding lectin produced by activated macrophages which binds and activates the fibroblasts [32]. The main biological role of galectin-3, as reported, is modulation of biological recognition processes, regulation of fibroblast proliferation and matrix synthesis that lead to fibrosis and extracellular remodeling. Results of recent studies have reported that galectin-3 is a biomarker that mediates an important link between inflammation and fibrosis, which play a pivotal role in CV remodeling [33]. The pathogenetic role of galectin-3 in the several setting of pressure overload, neuro-endocrine activation, hypertension, coronary artery disease / myocardial infarction, atrial fibrillation, and HF has strongly established [34-36].

Galectin-3 has emerged a predictive value for the onset of HF in apparently healthy patients and has been found being surrogate marker of a worse prognosis, mortality and re-admission in HF [22,23]. The results of the sub-study of COACH (The Coordinating Study Evaluating Outcomes of Advising and Counselling in Heart Failure) trial have shown that only galectin-3 was significantly associated with the absence of CV events at 180 days in patients with HF at low risk for death or HF re-hospitalization [37]. Therefore, authors indicated that this biomarker demonstrated an incremental value when added to the clinical risk model without NT-proBNP [37]. Overall, galectin-3 is obviously powerful prognosticator of death and re-hospitalization in HF patients at discharge from the hospital and in generally population individuals at higher risk of HF development.

Matricellular proteins

Matricellular proteins belong to family of multifunctional growth factors that are main components of the extracellular matrix which regulate bone developing, vascular remodelling, and tissue regeneration [38]. Although matricellular proteins (osteopontin, osteoprotegrin, osteonectin, thrombospondin) are surrogate biomarkers of vascular calcification and endothelia dysfunction in coronary artery disease, diabetes, obesity, atherosclerosis, dyslipidemia [39-41], the predictive role of these biomarkers in persons with aortic stenosis are still not understood because evidences are limited [42]. It has suggested that over production of matricellular proteins in aortic stenosis and CV diseases may consider as response to prevent vascular calcification [42]. However, the interrelation between CV mortality and circulating level of matricellular proteins in aortic stenosis in older adults is needed to be established.

Limitations of Previous Studies

There are not evidence exists that gait speed is optimal to test in older patients with aortic stenosis, although transthoracic echocardiography is the primary imaging modality that is used in clinical practice to assess the aortic valve morphology, the severity of aortic valve disease, and its repercussions on left ventricular function and aortic circulation [43]. Three-D echocardiography, dobutamine stress echocardiography and, more recently, aortic valve calcium scoring by multidetector computed tomography have been shown to be useful to confirm stenosis severity in the challenging subsets of patients with low-flow, low-gradient of aortic stenosis, despite interpretation of obtained results in older aortic stenosis patients with multiple comorbidities might be limited. Conventional pre- and perioperative surgical risk scores lack accuracy in risk stratification of older patients undergoing TAVI. Moreover, current data support hypothesis regarding use of hemodynamic parameters as sensitive predictors in symptomatic patients. Probably, using of cardiac biomarkers might extend our knowledge about CV risk in asymptomatic persons, whereas asymptomatic older patients are at higher CV risk and require rather cardiac functional status determining to enroll them in the group for further aortic valve replacement procedure. On the other hand, in geriatric population with aortic stenosis adding new biomarkers could increase the discriminative value of contemporary non-invasive hemodynamic characteristics to predict CV complications before non-cardiac surgery and performing of aortic valve replacement within long-term period. Indeed, the rationale for obtaining a preoperative and / or postoperative biomarker levels might have the utility when having a baseline Echo / Doppler parameters and functional cardiac status are abnormal, but there were not enough data to clinical decision making. Here one cannot discuss about pretreatment in this patient population, while the perspective of cardiac biomarkers utility might be determined in future. The next limitation of cardiac biomarker implementation is being low value care for older adults that might reduce the so-called clinical utility. It has suggested that the cardiac biomarkers are to be used in the specific contexts in high-income countries. This assumption requires more investigations using head-to-head comparison biomarkers with echo/ Doppler parameters, as well as patient’ clinical status. Overall, cardiac biomarker release signifying myocardial injury post-TAVI is common, yet its clinical impact within large TAVI cohort older persons receiving differing types of valve and procedural approaches is unknown.

Directions for further studies

Current clinical recommendations have reported that imaging modalities are essential for the staging and management of aortic valve disease. Because there are a large body of evidence regarding elevated brain natriuretic peptide levels as predictive biomarkers in symptomatic aortic stenosis patients after TAVI, one might resume that serial measurements of BNP and other markers of biomechanical stress, inflammation, cardiac injury, could be useful for risk stratification of the patients enrolled for TAVI. Moreover, cardiac biomarkers may probably have utility in risk stratification of asymptomatic individuals with aortic stenosis when closely corresponding between two-dimensional and Doppler echocardiographic parameters and clinical outcomes are absent. Other modalities such as biomarkers for the assessment of myocardial fibrosis, cardiac injury or inflammation might be promising to predict aortic stenosis progression and related outcomes in older individuals, but further research is necessary before implementation of these modalities into clinical practice.

In conclusion, two-dimensional and Doppler echocardiographies remain to be key tool for the evaluation and monitoring of aortic stenosis. Although there is no consensus on the prognostic value, sensitivity, and specificity of biomarkers to stratify older patients with aortic stenosis at risk, BNP / NT-proBNP, galectin-3, sST2
appear to be promising predictors of C death and clinical outcomes in this population. Whether combined biomarker approach might have an impact on clinical decision-making for risk stratification in aortic stenosis patients is still not understood and requires further investigations.
