Abstract

The olive tree (Olea europaea) is an arboreal crop that has developed coping and production capabilities in diverse soil and climatic conditions in Morocco. Therefore, it has become present in virtually the entire national territory.

The olive tree is sensitive to verticillium wilt. Several isolates of Verticillium dahliae Kleb collected from olive tree, in different regions of Morocco, were tested to determine their pathogenicity. The pathogenicity of forty eight Moroccans isolates of V. dahliae was tested vis-à-vis tomato, eggplant and pepper.

A continuum of pathogenicity degree was observed from more to less aggressive. Isolates from North and South had very high degrees of pathogenicity. Intercroppings tested also showed tolerance degree variation toward V. dahliae as follows pepper was least sensitive whereas tomato was most sensitive.

Keywords: Olea europaea; Verticillium dahliae; Intercropping; Pathogenicity; Pepper; Tomato; Eggplant

Introduction

The olive tree (Olea europaea), which is the species most cultivated around the Mediterranean Sea, offers enormous potential for Morocco. Because of his great power of adaptation, the olive tree is common in many parts of the country. The Olive National Plan aims at extending this crop to cover 106 ha in 2015 [1].

Unfortunately, the olive tree is susceptible to many diseases of bacterial, fungal and viral origins and numerous pests. Verticillium wilt, a vascular disease caused by Verticillium dahliae [2,3], is not only a threat to the olive tree but a lethal factor.

This soil fungus is widely distributed throughout the world, it occurs throughout the temperate and subtropical regions [4,5] and shows high variability in virulence, vegetative compatibility and morphology in particular.

This pathogen was reported for the first time in Morocco in the Meknes region [6]. It was met in all agricultural regions and especially in large market garden areas (Souss Massa Valley and Atlantic coast) and in the provinces of Meknes, Fez, Khemisset, Errachidia, Beni Mellal and Berkane [7].

Verticillium dahliae was encountered on tomato in many temperate and subtropical producing countries. This polyphage is able to infect more than 160 species of cultivated plants [8], Including several other solanaceous crops such as tobacco, potato, pepper and eggplant, which is particularly sensitive.

In Morocco, these crops are grown in areas ORMVA (Office de Mise en Valeur Agricole) and DPA (Direction Provinciale d’Agriculture) whose main market gardening areas are Sais (Meknes and Fez), Chaouia (Settat), the axis Rabat- Khemisset and Tetouan in the north (average of the last ten years)

In DPA areas most farmers cultivate tomato pepper and eggplant as intercropping in the olive. In this situation these three crops are subject to devastation of verticillium especially in the absence of effective treatment against this disease.

Hence the interest of our study in assessing the tolerance of these three intercroppings of olive vis-à-vis 48 Verticillium dahliae isolates collected from different Moroccan olive producing regions.

This assessment will help us classify our isolates according to their virulence on the one hand and on the other hand identify the most tolerant crop to Verticillium. These data can be used for future selection of resistant or tolerant intercropping to local pathogenic strains.

Materials and Methods

Origin of isolate

Forty-eight isolates of Verticillium dahliae isolated decayed from olive whorls and infested soils, to study their pathogenicity (Table 1). They were collected from different outbreaks of the disease in the major oil-producing regions in Morocco. Harvesting was done by series of surveys in the years 2010 and 2011. The isolation and study of crop characteristics on ten repetitions were performed in the laboratory of Plant Pathology of ENA (Meknes National School of Agriculture (Morocco)). Isolates were purified on PDA [9], positive isolates

develop a first hyaline mycelium becomes flocnneux, white and black [4] after 10 days of incubation (Figure 1). Blackening corresponds to the formation of microsclerotia (Photos 1 and 2).

Molecular characterization of all isolates was provided by conventional PCR [10] using the primer pair Na1/Na2 for confirmation of Verticillium genus and the couple P19/P22 for the characterization of the \textit{V. dahliae} species. The isolate is considered positive if it produces a band with a molecular weight 452 pd by the couple Na1/Na2 [3] (Figure 2) while the sample which sets the primer pair P19/P22 show a band 580 pb size characteristic of the species \textit{V. dahliae} (Photos 3 and 4) [10].

**Plant material**

The plants from tomatoes, eggplants and peppers used in our study belong to the standard varieties.

The choice of these varieties was based on their extensive use as...
intercroppings to the olive tree, and on the feat they are the most sold in the domestic market.

Inoculation of plant material by Verticillium dahliae

Preparation of the spore solution: The colonies were scraped with a sterile blade superficially after addition of a few drops of sterile distilled water. The conidial suspensions obtained were filtered through filter paper to remove hyphal fragments.

The concentration of the suspension was adjusted using a hématocymètre. The final concentration was determined by calculating the average of 5 to 10 individual counts. Once the concentration was calculated, it is adjusted with dilutions to obtain the final working concentration (10^6) using the following formula [11]:

\[
\text{Concentration (conidia/ml)} = \frac{\text{Number of conidia} \times 1000}{50}
\]

Experimental monitoring protocol: The seeds were placed in jars containing 50% sterile soil and 50% sterile soil. For each plant species there were 136 pots containing 10 seeds each. For each isolate two pots were watered with 50 ml of sterile distilled water whereas the other two were watered with 50 ml of the spore suspension. Four other pots of each plant species were considered as control. The temperature was 24 ± 1°C under natural night.

Starting from the third week after sowing readings were made every week. After six weeks we inoculated two previously untreated pots containing cuttings of the studied crops by the same isolates.

All the results were collected on the same date two weeks after the second inoculation.

Monitored parameters during the trial

External symptoms of the disease were evaluated by the severity index, made according to the scale of Thanassoulopoulos et al. [12] adapted to the treated crops. 0: healthy plant, 1: low defoliation of plants, 2 death of less than 50% of plants, 3: 60% of dead plants, 4: 100% death of plants.

Internal symptoms of verticillium wilt were assessed according to the scale of Subbarao et al. [13] by two indices:
- Root Browning Index (RBI): 1: normal appearance, 2 browning of less than 10% of roots, 3 browning about 50% of roots, 4 intensive browning and short root system [13].
- Stem Browning Index (SBI): 1: no browning, 2: browning of 25%, 3: about 50% brown, 4: Browning of over 50% [13].

Reisolation of V. dahliae

Re-isolation was made from inoculated plants. To do so, fragments of the stem, leaves and roots were recovered and then disinfected in a sodium hypochlorite solution (1/3) for 5 min and then rinsed three times with sterile distilled water. The fragments were planted on PDA medium with streptomycin (25 mg/ml) and chloramphenicol (25 mg/ml). The culture plats were incubated for 10-15 days at 22°C.

Statistical analysis

Data were analysed using ANOVA and multiple linear regression procedures of the R software [14].

Results

External symptoms

The factors considered in this study were highly correlated and significantly influenced the mortality rate (Table 2).

The interaction region*stage was significant (p=3.88410^-8). The three species reacted differently to the fungus in the tow the inoculation stage. Seedlings of eggplant, tomatoes and peppers inoculated by V. dahliae at the seeds stage were severely affected by this pathogen. Plants inoculated at cutting stage have shown tolerance vis-à-vis V. dahliae (Figure 1).

Figure 1 shows that 50% of the inoculated plants were at the stage cutting a zero mortality, 25% showed a level of between 0 and 24%, the rest have a rate of between 24 and 50%. While at seedling stage, 75% of the plants have a mortality rate of between 50 and 100%. Only 25% have a lower 50% rate.

Compared to control plants, the three crops responded to inoculation with the agent. This response is significantly different among crops (p<2.2 10^-16).

Tomato, eggplant and pepper had a high, average and low mortality

Soumia D, Elali CA, Said A, Mohammed D (2014) Assessment of the Tolerance Level of Three Olive Intercroppings (Tomato, Eggplant and
Verticillium dahliae

In fact browning indexes of the three cultures vis-à-vis the various
isolates of V. dahlia had a very highly significant difference. And
isolates of the pathogen affected different cribro vascular vessels of

rate respectively (Figure 3).

Based on mortality, the different regions had different pathogenicity
city degrees (p<2.293 10⁻⁴). Isolates collected from Taounate region showed the highest
mortality rate, followed by isolate from Beni Mellal. Isolates of the
central region were characterized by a high average virulence.

Olive-growing regions of the North East are characterized by
moderately severe isolates.

The lowest mortality was recorded for isolates of olive-growing
regions of center facing a recent incidence of Verticillium wilt
(Ouisslane, Agourai) (Figure 2). In parallel to the study of mortality severity indices were assigned to
each studied factor combination. This index was significantly affected
by the three factors considered (p <0.0001196). The linear regression
between the variables monitored during our study showed that index
significant differences were explained by mortality (p<2.10⁻¹⁶, R-
squared: 0.8615).

In our study tracking numbers of fallen leaves was impossible given
the virulence of isolates vis-à-vis the treated plants, resulting in the
death of most infested plants before the fall of leaves. For control plants
no defoliation was recorded.

Plants internal response vis-à-vis isolates of Verticillium dahliae

At the stem, browning was not regularly observed in all plants of
the same batch. For the same isolate, some plants showed a clear
browning while in other browning was virtually absent.

This index was highly influenced by the three factors taken into
consideration (p = 0.0001717) (Table 3).

To estimate the pathogenicity of forty eight isolates of Verticillium dahliae
collected from different olive-growing regions of Morocco, and to compare the response to V. dahlia of three olive intercoppings,
four parameters were considered, namely the mortality rate, severity
index, browning of root and aerial vascular tissues and distribution of
pathogen in different parts of the plant.

| Table 3: Test the effect of three factors (culture, stage and region) on the Index Browning at the Root (RBI). |

the host. Isolates collected in the south zone were characterized by an
average index of browning, followed by isolates from North-East and the
Fez region. The highest browning index was recorded in North
isolates (Taounate) and central zone.

Views culture, tomato plants showed a very high level of browning
compared to eggplant while the pepper was the least affected.
The fungus slightly affected in the plants inoculated at the cutting
stage. The plants off the three species inoculated at the seed stage had a
relatively high browning.

The browning in the roots of these three plants varied very
significantly varied depending on the plant species, the stage of
inoculation and origin of isolates. The browning index in the roots
followed the same trend as in the stems in the three species (p<2.10⁻¹⁶,
R-squared: 0.9965).

The re-isolation of the pathogen

In order to confirm and determine the distribution of the fungus
in different parts of the inoculated plant, re-isolation of the pathogen
was performed. The reisolation percentage was significant differences
among the plants parts in all three species (p<2.10⁻¹⁶). However, the
percentage of positive reisolation for Forty-eight isolates showed no
significant difference. This means that all isolates have a percentage high
enough to allow to attribute the observed symptoms to Verticillium dahliae (Table 4).

Discussion

To estimate the pathogenicity of forty eight isolates of Verticillium dahliae
collected from different olive-growing regions of Morocco, and to compare the response to V. dahlia of three olive intercoppings,
four parameters were considered, namely the mortality rate, severity
index, browning of root and aerial vascular tissues and distribution of
pathogen in different parts of the plant.

Isolates of the North, the central zone and Beni Mellal showed the
most severe symptoms of verticillium wilt, which is consistent with the
results obtained by Cherrb et al. [8]. Based on this index tomatoes have
high sensitivity with respect to all isolates.

Regarding the rate of mortality, the three species showed a tolerance to
the disease when the inoculation was performed at cutting stage.
Plants whose seedlings were inoculated in advance were susceptible to verticillium wilt. This significant difference between the stages of inoculation can be explained by the natural defense responses of plants [15]. In fact, the various plants mechanisms of grow in the presence of natural defense elicitors [16,17]. The presence of V. dahliae, an inducer of SAR (Systemic Acquired Resistance) [18], triggers and enhances resistance proteins synthesis in roots.

This idea has already been confirmed by the study of the roots of tomatoes for the revelation of the induction of SAR in the presence of Pythium oligandrum conducted by Picard and Tirilly [19].

The browning index of vascular tissues revealed a significant difference from one isolate to another. For some plants, this index was zero. However, the lack of browning does not mean the absence of the pathogen [8]. In fact, several isolates V. dahliae were positive in olive branches that had a healthy appearance.

According to Woolliams [20], the distribution of the pathogen is heterogeneous in the host tissues. The positive re-isolation of the pathogen decreases gradually as one move away from the leaves to the roots. Results similar to ours were reported by other authors about V. dahliae in several plants [12,21-25].

The combination of the various parameters studied showed that in general, the observed results were consistent. The degree of pathogenicity varied along a continuum from the most aggressive to the least aggressive. Isolates from North and South have very high degrees of pathogenicity.

Intercroppings tested also showed a variation in the degree of tolerance vis-à-vis V. dahliae. Pepper was on the top of the list while tomato showed a very high sensitivity. The presence of these vegetable crops in the original areas of pathogen influences the degree of pathogenicity of isolates on olive cultivation [8].

In light of these results, we recommend the following:
- The application of technical and cultural prophylactic.
- Avoid introduction of tomatoes, peppers and eggplant intercropped with olive.
- Perform preliminary analysis of soil before the implementation of these three cultures.
- Extend the study to other interlayers olive plants.
- Encourage varietal selection at national level of vegetable crops and olive.
