Abstract
A facile protocol, which involves topical application of recombinant human Epidermal Growth Factor (rhEGF), was previously developed by our group and shown to be effective in treating diabetic foot ulcers, when working in conjunction with debridement surgery. In this communication, using the same approach of rhEGF application, despite the absence of debridement, our findings demonstrated that the protocol worked equally well on a hard-to-heal wound, which remained unhealed subsequent to surgical removal of the great saphenous vein from the left thigh of a diabetic patient. After treatment with rhEGF for 10 d, the wound was shown to heal readily and finally achieved complete healing. The success of rhEGF in the healing process is concluded to be attributable to both the fine quality and sufficient dosage of rhEGF.

Keywords: Recombinant human epidermal growth factor; Escherichia coli; Excretion; Hard-to heal wounds; Topical application; Diabetes mellitus

Abbreviations
DFU: Diabetic Foot Ulcers; rhEGF: Recombinant human Epidermal Growth Factor employed in this study; hEGF: Human Epidermal Growth Factor produced by other protocols; VT: Designation of the diabetic patient concerned in this study; CAD: Coronary Artery Disease; CAGB: Coronary Artery Bypass Grafting: EVH: Endoscopic Vein Harvesting; SJS: Steven Johnson Syndrome

Introduction
Patients suffering from Diabetes mellitus are potentially afflicted with many health-threatening complications. Among them, the presence of diabetic neuropathy and peripheral vascular damage may lead to the development of Diabetic Foot Ulcers (DFU), which results in a 5- to 50-fold higher risk of non-traumatic amputation when compared with normal individuals [1]. On the other hand, vascular damage causes coronary atherosclerosis, which may lead to myocardial infarction. Since good blood circulation is important for the healing of existing wounds and prevention of new wound development [2], cardiovascular disease has an undesirable effect on wound healing.

My group has pioneered the application of recombinant human Epidermal Growth Factor (rhEGF) to the treatment of DFU and complex wounds. In the early 2000s, employing rhEGF prepared from an engineered Escherichia coli excretion system [3-6], and working with a local hospital, United Christian Hospital, in Hong Kong, we reported the use of rhEGF to successfully enhance the healing rate of DFU [7]. In our protocol, rhEGF resuspended in aqueous cream was demonstrated to be able to dramatically improve the efficacy of complete recovery of DFU wounds. Specifically, it improved from a rate of 42.1% obtained using only debridement surgery to a much increased efficiency of 95%, achieved through first debridement and subsequently topical treatment with 0.04% (w/w) rhEGF, but not a lower concentration of rhEGF with 0.02% (w/w) of it [7]. Subsequently, patent protection has also been obtained for the findings reported in this facile treatment process [8-12].

In addition to treating DFU [7], 0.04% (w/w) rhEGF has also been applied successfully to cure other severe wounds, including Steven Johnson Syndrome [13] and bedsores [8-12]. All of these applications support the view that rhEGF is not only an effective means for wound healing, but it may be highly versatile in managing differently difficult-to-heal wounds. In this communication, the application of rhEGF to an effective treatment of a recalcitrant wound, which resulted from the surgical removal of the great saphenous vein of the left thigh of a diabetic patient, is reported. Prior to the curing process, the wound suffered bacterial infections, thus rendering the chance of potential gangrene, which might lead to life-threatening conditions if delays in treatment occurred.

Results and Discussion
The patient was a 64-year-old male, designated “VT”, who had suffered from Type 2 diabetes mellitus for 7 years. By taking prescribed drugs, metformin and glyburide, VT’s blood sugar readings varied between 6 and 10 mmol l⁻¹ before he was diagnosed with Coronary Artery Disease (CAD). To cure this potentially fatal heart disease, VT, who had never received any cardiac surgery previously, was recommended to undertake the treatment of Coronary Artery Bypass Grafting (CABG), in which three coronary arteries were required to be bypassed during surgery. To attain three vessels required in CABG, a 48 cm great saphenous vein was harvested from VT’s left thigh (Figure 1), using the endoscopic method [14], and then employed for the surgical bypass. As a result of operations, four incisions, spreading from the groin to the knee and with each wound measuring approximately 4-6 cm × 0.8 cm, existed on his left thigh (Figure 1).

The CABG surgery progressed quite favorably. VT recovered swiftly from CAD after treatment and was discharged from the hospital 4d after the surgery. At that point, despite VT’s diabetic complications, all four incision wounds located on his left thigh appeared to heal well.

However, probably due to movements of the left leg, in about the 3rd week or so after VT returned home from the hospital, the 2nd wound from the knee (Figure 1) ruptured. While recovery of the remaining

three wounds progressed quite well, the 2\textsuperscript{nd} wound did not exhibit any improvement in healing. In another 4 weeks, while the 1\textsuperscript{st}, 3\textsuperscript{rd} and 4\textsuperscript{th} wounds had almost completely healed, the 2\textsuperscript{nd} wound remained not only unhealed, but also developed small sloughs, despite being treated with \textit{cloxacillin}, an antibiotic prescribed by VT’s family doctor for him to take to prevent bacterial infections.

Despite taking \textit{cloxacillin} and being monitored by a doctor, the 2\textsuperscript{nd} wound on VT’s left thigh refused to heal (Figure 2). It appeared that further delays in treating the wound might induce life-threatening ulceration, which might lead finally to leg amputation. VT and his family were apprehensive, and they approached us for assistance seven weeks after Endoscopic Vein Harvesting (EVH).

With our previous experience and success in healing DFU, a facile protocol (Figure 3) was promptly designed to treat VT’s unhealed 2\textsuperscript{nd} wound on his left thigh [7]. As in treating DFU, a simple topical procedure was proposed to be employed for the unhealed wound (Figure 3). However, unlike DFU, VT’s wound was relatively “clean”, i.e., it appeared to be only mildly infected. Moreover, there was not much dead tissue in or around the wound, thus precluding the requirement of a debridement procedure for wound cleansing. VT’s wound was treated twice a day with an aqueous cream containing 0.04% (w/w) rhEGF (Figure 3), which was previously utilized successfully in treating DFU [7], bedsores [8-12] and SJS [13]. The result was unexpectedly positive. VT’s wound showed efficient recovery, and thus rhEGF application was stopped after the 10\textsuperscript{th} day of treatment. Over approximately 6 d, despite the absence of rhEGF treatment, VT’s wound continued to recover and subsequently achieved complete healing (Figure 2). Another point worth noting is that the wound healed not only efficiently, but apparently also quite smoothly, thus avoiding the formation of a hypertrophic scar on the skin (Figure 2).

Previously, we reported that rhEGF was employed successfully in treating various complex wounds including DFU [7], bedsores [8-12], and SJS [13]. In the current study, it was again well demonstrated that rhEGF was effective in promoting treatment of a seriously deteriorating wound of a diabetic patient (Figure 1) which refused to heal seven weeks after the surgical process. The high efficacy of rhEGF in wound healing was likely attributable to two important factors, firstly, to the high concentration, 0.04% (w/w) rhEGF, which was revealed to be above the minimum effective dosage in treating DFU [7]. Secondly, the fine quality of rhEGF might also play a crucial role. The excretion system engineered by our group has been utilized to efficiently produce rhEGF, which has been shown to possess not only potent bioactivity, but also exceptional purity [5]. Both the high levels of bioactivity and purity of rhEGF were concluded to have critical impact on curing the recalcitrant wound on VT’s thigh (Figure 2).

Given the beneficial applications of hEGF in treating various wounds, the possibility that hEGF, which has a potent proliferative effect on skin cells, might stimulate malignancy has always constituted a subject of concern. However, vast amounts of data have been gathered about applications of hEGF in treating a wide variety of wounds through various routes of administration [15]. Interestingly, despite the reports of numerous successful treatments in these studies, none of them has offered significant evidence to support that exogenous introduction of hEGF would promote carcinogenesis [15,16]. On the other hand, mutants of EGF receptor, which are able to undertake effect on skin cells, might stimulate malignancy has always constituted a subject of concern. derivatives, in stimulating malignancy. Since rhEGF shares the same identity as native hEGF [5], it is believed that the former will be as safe as the latter in promoting cell growth.

A wide range of expression systems have been developed for the production of hEGF [17,18], which comprised a collection of structurally heterogeneous products [17,18]. In fact, many of these systems were able to produce only structural derivatives of mature native hEGF [17,18], which might not be as active or stable as rhEGF [3-6]. The later product was characterized to possess an authentic structure, thus sharing the same primary sequence as mature native hEGF of human origin [5]. Moreover, hEGF produced by the majority of the protocols, which were designed essentially for intracellular protein production, were likely contaminated by endogenous proteins and/or endotoxins of the host cells. These contaminants could seriously impede the bioactivity and stability of hEGF. For example, it has been asserted that many of these protocols have resulted in even non-active hEGF [19].

Conclusion

CAD, similar to DFU, is a common side effect of diabetes. CABG is often considered a solution to treat CAD. When an incision resulting from saphenous venous harvesting refused to heal, gangrene may develop and lead to life-threatening complications. In this report, as demonstrated previously by our group in treating DFU, topical treatment with 0.04% (w/w) rhEGF is shown to be equally effective in promoting healing of a hard-to-heal surgical wound derived from EVH.
