ABSTRACT

Invasive *Trichosporon inkin* fungal infections are rare and unusual, occurring nearly exclusively in immunocompromised patients experiencing prolonged neutropenia during treatment of malignant hemopathies or other immunodeficiency conditions. We report a case of a 27-year-old patient with severe aplastic anemia who developed *Trichosporon inkin* sepsis with skin lesions during aplasia after myeloablative allogeneic stem cell transplant. He was treated with liposomal amphotericin B but died from multiple organ failure. We then discuss the epidemiological, clinical and therapeutic features of these serious fungal infections compared to the published data.

Keywords: *Trichosporon inkin*; Aplastic anemia; Invasive fungal infection; Trichosporonosis; Hemopathy; Immunodeficiency; Antifungal therapy basidiomycetes

INTRODUCTION

Fungal infections are an important cause of death in immunocompromised patients, and particularly with hematologic disease. The most common fungal infections are invasive aspergillosis and invasive candidiasis [1,2] but mucormycosis are one of the most dreaded disease. Here, we want to approach about Trichosporonose, least well-known, but which have devastating effects. Currently, no standard recommendations for *Trichosporon spp* antifungal prophylaxis and treatment exist.

CLINICAL EVOLUTION

We report medical history of a 27 years old man of Turkish origin with no relevant medical history, who has been admitted to our haematology unit for a severe idiopathic aplastic anemia, according to standard diagnostic and severity criteria [3-5], (Thrombopenia 6 Giga/L; Hb 12 g/dL, Reticulocyte 12 G/L-bone marrow hypocellularity<15%, absolute neutrophil count 1.3 G/L).

An induction by cyclosporine 2 mg/kg twice daily associated with daily granulocyte colony-stimulating factors (lenograstim, G-CSF) is started, but the course has been unfavourable, with a persistence of medullary depression and quick appearance of very severe aplastic anemia criteria: Hb 8 g/dL, reticulocytes 3 G/L, platelets 20 G/L, absolute neutrophil count 0 G/L on October 2012.

The patient presented with fever and development of herpetic gingivostomatitis. The patient's room was located in the leukaemia unit and was a positive pressure ventilation clean room. The explorations fund no documentation. The patient was treated with broad spectrum antibiotherapy (piperacillin/tazobactam) with absence of bacteriological documentation.

At day 14, an anal cellulitis appeared with perineal pains and persistence of fever. The evolution is complicated with several bacteraemia documented with *Stenotrophomonas maltophilia* and *Staphylococcus epidermidis* Meticilline-resistant. Unfortunately, there was no possibility of surgical management of this perineal cellulitis, no surgical indication, because of the thrombocytopenia and uncollected skin damage. The patient received different anti-infectious therapies (Figure 1).

At day 18, the patient presented a pneumonitis characterised by an interstitial syndrome. Because of a suspicious positive aspergillosis antigenemy we treated the patient by VORICONAZOLE 4 mg/kg twice a day switched for CASPOFUNGINE 50 mg per day (hepatitis toxicity), No broncho-alveolar lavage was performed at this time. The evolution was favourable under this treatment.

Because of persistent medullary abnormalities and multiple infectious complications, an pheno-identical 10/10 allogeneic stem cell transplant was performed 20 days after the initial ciclosporin-

based therapy; the conditioning was non-myeloablative, with Cyclophosphamide 300 mg/m²/d and horse anti-thymocyte globulin 40 mg per kg per day.

At day 20, the patient has presented a new infectious pneumonitis, characterized by bilateral interstitial and micro nodular infiltrates and an apical predominance. The broncho-alveolar lavage revealed a small lymphocytosis, and the bacteriological and mycological cultures remained negative. The CASPOFUNGINE was switched to VORICONAZOLE 4 mg/kg twice a day (after loading dose 6 mg/kg twice a day once) in ad of the antibiotics.

Then, at day 43, the patients developed skin nodules on the left foot, then an extension until the left thigh. At this time, the patient benefited from a large anti-infectious therapy (Figure 1). The multiple positivity of samples proved the disseminated Trichosporinose: The skin biopsy fund a fibrinous necrosis associated with histiocytes and septate and budding fungal structures, arguments for alternariose or trichosporinose. One blood culture (at day 66) was positive to *Trichosporon inkin*, which was identified by mass spectrometry (MALDI-TOF), as well as an anal sample. The transthoracic echography did not find argument for endocarditis or myocarditis. We added AMBISOME 3 mg/kg/day to VORICONAZOLE at day 52 to broaden the spectrum and used in dual therapy.

Alternatively, the patient developed a CMV viremia, probably due to a reactivation (positive CMV serologic status of the recipient). It was treated in the first place by GANCICLOVIR 10 mg/kg twice a day, switched by Foscavir because of the persistence of the significant viral load. Before the transplant, the initial CMV serologic status for CMV the recipient was positive, which allowed a negotiation of the viremia.

At the day 80, the patient was transferred in medical reanimation for an acute respiratory distress syndrome, in relation with an acute cardiac deficiency due to a myocarditis. The viral aetiology was excluded because of the decrease of the CMV viral load. The privileged hypothesis was fungal, and potentially due to *Trichosporon*, because of the disseminated character, the cardiac tropism and the slowly good evolution under treatment. The patient went out of apnea at day 110.

In front of the favourable evolution and because of persistent fever, the antibiotic and antifungal drugs, except FOSCAVIR (decreased viral load) were stopped in order to make new infectious samples. Unfortunately, the patient developed a febrile pancytopenia, without argument for a macrophage activation syndrome, and a skin rash. No microbiological documentation was found. Antibiotics PIPERACILLINE-TAZOBACTAM 4 g four times a day VANCOMYCINE 30 mg/kg in continuous and AMIKACINE are reintroduced. The new skin biopsy was in favour of a drug eruption. The VANCOMYCINE is switched by DAPTOMYCINE 4 mg/kg once a day, without improvement of the skin. The thoracic tomography showed an aggravation of pulmonary lesions, with an excavation. The patient died for a new acute respiratory distress due to an acute cardiac insufficiency, and multivisceral organ failure.

DISCUSSION

This case shows the diagnostic difficulties of this infection and its gravity. Although a large anti-infectious therapy, the therapeutic stain ineffective. There is no consensus on the treatment of this.

Invasive fungal infections caused by *Trichosporon spp* are a deadly disease, with death rates of up to 80% in immunocompromised patients [6,7].

Trichosporon species are the causative agents of cutaneous infections like white piedra or hypersensitivity pneumonitis syndrome in immunocompetent patients, but they can be involved in invasive mycoses in immunodeficient patients, like haematological malignancies or solid tumours or AIDS [6-9].

Trichosporon asahii appears to be much more common in cases of systemic mycosis, while other *Trichosporon* species are involved in superficial skin lesions [6,7]. Ramos et al. study shows a high fungal burden in kidneys with *T.asteroides* than *T.asahii* that is in agreement with this observation [10]. However; *Trichosporon inkin* is the common agent of superficial trichosporinosis. But in rare cases of systemic disease, it can be isolated, and in this case, is associated with catheter infections [1,2,6,7].

1,3-Beta-D-glucan is a polysaccharide component specific to fungal cell wall. The assays have been reported to be useful for the early

diagnosis and therapeutic monitoring of various invasive fungal infections, but none proves the interest in trichosporinose.

Trichosporon belong to amorphous basidiomycetes, characterised by spores, formed by septate strands and anastomosed branches. They are found in soil, water, decomposing matter and bird and bat dropping, but also in cheese or scarab. They belong to human micro biome, especially of the skin (essentially scrotum, perianal and inguinal sites), gastrointestinal and upper respiratory tracts. The transmission mode is unknown.

51 clinical isolate strains are identified, and 16 of which are able to infect humans [9]. Morphological and biochemical methodologies were unable to differentiate among the *Trichosporon* species. Several methods exist to identify the samples, like the physiological patterns, sequence polymorphisms of the internal transcribe spacer (ITS), intergenic spacer regions (IGS) of the rDNA genes.

Trichosporon spp. produce a biofilm, which is consisted of masses of bastoconidia, anthroconidia, pseudohyphae and long and short hyphae, featuring multi-layer cell structures, closely associated [6].

These cells produced and secreted enzymes, like extracellular proteases [6]. Aguiar et al. hypothesised that the secretory aspartic protease is responsible of the antimicrobial resistance, as well as high levels of extracellular DNA. They can produce this biofilm in blood, urine and on skin.

The study of the fungal biofilm becomes more and more important for clinicians, because of its capability to increase mortality. Several techniques are used, like the crystal violet staining method or SEM (Scanning electron microscopy) [9,11].

In another side, *Trichosporon* species are able to produce glucuronoxylomannan, a capsular polysaccharide, like *Cryptococcus neoformans*, and it seems to play a probable role in mechanism of resistance [12,13].

It is generally accepted that according to different species, the virulence and resistance mechanisms are different. *Trichosporon spp.* is resistant to traditional antifungal drugs like Amphotericine B, Caspofungine, Fluconazole and Itraconazole, but relatively susceptible to Voriconazole. But, in some cases, we see resistance to azoles, due to high tolerance biofilm (Table 1).

Indeed, in his article, Chagas-Neto reported the presence of resistance of all antifungal agents tested (included Voriconazole), independent of genotype or isolation site. Moreover, the serum concentrations are lower than the MIC values.

Table 1: Susceptibility to antifungals.

	CMI (µg/mL)
Voriconazole	0.032
Amphotericine B liposomale	0.5
5 fluorocytosine	>32
Posaconazole	0.094
Fluconazole	1
Itraconazole	0.75

CONCLUSION

In conclusion, to our knowledge this is the first published case of fatal invasive fungal infection with *Trichosporon inkin* in an allogeneic stem cell transplant recipient that was not successfully controlled with liposomal amphotericin B and voriconazole. *Trichosporon spp.* seems to be an emerging, opportunistic agent in immunocompromised patients with malignant haematological disease. Further research is needed to determine the best antifungal strategy, the optimal time and posology of treatment, and to identify the mode of dissemination of this fungal agent, the incubation period and mode of transmission in immunocompromised patients, and risk factors.
