Abstract
Objective: The objective of this meta-analysis was to determine the efficacy of psychological treatments for depression and anxiety disorders in low- and middle-income countries (LAMIC). Method: Meta-analysis of randomized controlled trials on psychological treatment of depression and anxiety disorders in low- and middle-income countries using an existing database (www.evidencebasedpsychotherapies.org), PubMed, Embase, PsycINFO, Dissertation Abstracts International and the Cochrane Central Register of Controlled Trials were searched for studies published in all languages. Additional studies were identified from reference lists of found studies. Randomized controlled trials in which a psychological intervention for anxiety or depression was compared to a control condition (care-as-usual, waiting list, placebo, or another control group) were included. The randomized controlled trials needed to be conducted in a LAMIC country (classification of LAMIC countries according to the World Bank’s list of economies) to be eligible for inclusion in the meta-analysis. Psychological treatments were defined as interventions in which the core element of treatment consisted of verbal communication between a therapist and a patient. Results: Seventeen studies met our inclusion criteria, with a total of 3,010 participants. The mean standardized difference between the treatment and control groups at post-test was 1.02 (95% CI: 0.76–1.28) which corresponds well with the effects found in high-income countries. Conclusion: These results indicate that psychological treatments of depression and anxiety disorders are also effective in LAMIC countries, and may encourage global dissemination of these interventions.

Introduction
Depression and anxiety disorders are highly prevalent worldwide. On a global scale, approximately 150 million people suffer from a major depressive disorder at any moment, and almost a million commit suicide each year. These common mental disorders are associated with a significantly impaired quality of life, with excess mortality, substantial societal costs, and a considerable burden of disease. Major depression was ranked as the fourth most disabling medical disorder worldwide in 1990 and 2002, and is expected to be the second most disabling disorder after HIV/AIDS in 2030.

Despite the high worldwide prevalence and associated burden of common mental disorders, the need for treatment is not always met. The World Health Organization (WHO) indicates that the treatment gap for mental disorders in developed countries is 30-50% and in low- and middle-income countries (LAMIC) 70-80%. This gap is mainly caused by a scarcity of human, mental health and financial resources, as a result of financial and policy factors in low and middle-income countries. The inequity in access to mental health care that is prevalent in most low and middle-income countries is an important factor as well. The socio-economic status of an individual determines whether he or she has access to facilities or not. The high prevalence of stigma and discrimination causes people to abstain from seeking help even if they do have access.

Most LAMIC countries give low priority to mental health policies, with two-thirds of these countries having no mental health policy at all. Around a third of countries do not have a...
mental health budget and of those who do have a designated budget, 21% spend less than 1% of their total health budget on mental health.15

Research has indicated that many people who are seeking help in LAMI countries are not treated with evidence-based interventions.16 One reason for this is that many of the countries with an allocated budget are not informed by research evidence on mental health needs and efficacious treatments within the countries. This can cause policies to emphasize on specific service delivery programs for which no success is demonstrated.

Therefore, most of the low and middle income countries do not allocate adequate resources and are ill-equipped to deal with mental health needs.17 The scarcity of useful research on the connection between resources consumed and outcomes achieved makes it often mentioned as a barrier to convince LAMI countries to invest in mental health care.

The evidence indicating adequate treatments for anxiety and depression, is mostly obtained from studies in high-income countries, and this may contribute to difficulty in convincing policy-makers in LAMI countries to devote more resources to this area. While more than 85% of the world’s population lives in LAMI countries18, only 6% of the mental health publications (dating from 1992-2001) focus on LAMI countries.19 Between 2002 and 2004 only 3.7% of published papers emerged from low and middle-income countries.20 Furthermore, there are several possible reasons why data on psychotherapy from high-income countries may not be generalizable to LAMI. First, cultural factors can influence the risks factors for common mental disorders as well as the conceptualization of these disorders by both patient and care provider. The attitudes of people in developed and developing countries often differ regarding the kind of help that is needed to resolve a disorder.21 Explanatory models in many low and middle-income countries may be less likely to acknowledge the role of psychobiological factors in psychological distress. This may affect the attitudes of people with regard to what kind of help is needed and the acceptability of mental health interventions. Second, the infrastructure of health systems in high-income and LAMI countries can diverge extensively. The applicability of treatment research from developed to LAMI countries can be influenced by the scarcity of mental health manpower, the growth of the private medical sector, and the rising health costs and changing health care financing systems.21

An important type of treatment that may be useful in reducing the disease burden of depression and anxiety disorders in LAMI countries, are psychological treatments. These treatments have been well-studied in high-income countries and a considerable number of well-designed studies have shown that these interventions are effective in the treatment of common mental disorders.22-24 Furthermore, most patients in high-income countries prefer psychological treatments above pharmacotherapy for depression.25 It is not clear, however, whether these treatments are also effective in LAMI countries.

In the current review, we present the results of a meta-analysis of psychological treatments for anxiety and depression in LAMI countries. Although some traditional reviews have been published26,27, no meta-analytic study has been conducted yet.

Methods

Search strategy and selection of studies

Studies were identified using several methods. First, we used a large database of studies on the psychological treatments of depression. This database, how it was developed and the methods used, have been described in detail elsewhere.28 Key materials, overviews of the goals and mission, and an overview of all other meta-analyses which have used this database can be downloaded from the website for this project (www.evidencebasedpsychotherapies.org). In brief, the database was developed through a comprehensive literature search (of works dating from 1966 to January 2009) in which we examined a total of 9,981 abstracts in: Psycinfo (2,439), Pubmed (1,629 abstracts), Embase (2,606), the Cochrane Central Register of Controlled Trials (2,337), and in order to identify unpublished studies, Dissertation Abstracts International (950 abstracts). We identified these abstracts by combining terms indicative of psychological treatment and depression. For this database, we also collected the primary studies from 42 earlier meta-analyses of psychological treatments for depression29 and checked the references of included studies. We retrieved a total of 1,036 papers, chapters and dissertations for further study. These documents were studied, and we selected the ones that met our inclusion criteria.

Second, we conducted an additional literature search in different databases. In total 448 abstracts were examined in Psycinfo (49), Pubmed (106), Embase (281) and Cochrane’s Central Register of Controlled Trials (12). Databases were searched by combining terms indicative of controlled trial, target problems (depression and each of the anxiety disorders), country (Low- and middle-income country, LAMI, developing country, all the specific LAMI countries are used as key word as well23) and psychological treatment. Both keywords and text words were used for all the searches. We also checked the included studies in earlier reviews.26,27 Furthermore, we checked the reference lists of included studies.

Studies were included if they met the following criteria: (1) randomized controlled trial in which a psychological intervention was compared to a control condition (care-as-usual, waiting list, placebo, or another control group); (2) the treatment was aimed at patients with depression, anxiety or both; and (3) the study was conducted in a LAMI country (classification of LAMI countries according to the World Bank’s list of economies23).

Psychological treatments were defined as interventions in which the core element of treatment consisted of verbal communication between a therapist and a patient. Studies in which the psychological intervention could not be discerned from other elements of the intervention were excluded (such as managed care interventions and disease management programs), and studies on inpatients. We also excluded studies aimed at maintenance treatments and relapse prevention. Comorbid general medical or psychiatric disorders were not used as an exclusion criterion. No language restrictions were applied. Two authors extracted data on the year of publication, geographic region of the study, target disorder, study design, population characteristics, number of patients in each treatment group, type of intervention used and clinical outcome measures from each study.
We assessed the validity of included studies using the “risk of bias assessment tool”, developed by the Cochrane Collaboration, which focused on whether the allocation sequence was generated adequately, allocation concealment, whether knowledge of the allocated interventions was adequately prevented during the study, the addressing of incomplete outcome data, whether the reports of the study are free of suggestion of selective outcome reporting, and other risks of bias.

Meta-analyses
For each comparison between a psychological treatment and a control group, we calculated the standardized mean difference (Cohen’s d) indicating the difference between the two groups at post-test. We calculated these effect sizes by subtracting (at post-test) the average score of the psychotherapy group from the average score of the control group, and dividing the result by the pooled standard deviations of the two groups. Effect sizes of 0.8 can be assumed to be large, while effect sizes of 0.5 are moderate, and effect sizes of 0.2 are considered small. We applied the correction for small sample size as suggested by Hedges and Olkin. In the calculations of effect sizes we only used those instruments that explicitly measured symptoms of depression or anxiety. If more than one depression or anxiety measure was used, the mean of the effect sizes was calculated, so that each study (or contrast group) only provided one effect size. We only used the effect sizes indicating the differences between the psychological treatment and the control groups at post-test. We decided not to examine the effects at follow-up, because the number of effect sizes was relatively low (6 studies). In addition, the follow-up period differed considerably among these studies (ranging from 3 months to one year).

To calculate pooled mean effect sizes, we used the computer program Comprehensive Meta-Analysis (version 2.2.021). Because we expected considerable heterogeneity among the studies, we decided to calculate mean effect sizes with the random effects model. In the random effects model it is assumed that the included studies are drawn from ‘populations’ of studies that differ from each other systematically (heterogeneity). In this model, the effect sizes resulting from included studies not only differ because of the random error within studies, but also because of true variation in effect size from one study to the next. Publication bias was tested by using Duval and Tweedie’s trim and fill procedure, which yields an estimate of the effect size after the publication bias has been taken into account. As an indicator of homogeneity, we calculated the F-statistic which is an indicator of heterogeneity in percentages. A value of 0% indicates no observed heterogeneity, and larger values show increasing heterogeneity, with 25% as low, 50% as moderate, and 75% as high heterogeneity. We also calculated the Q-statistic, but only report whether this was significant or not. Because the effect size is difficult to interpret from a clinical perspective we also calculated the numbers-needed-to-be-treated (NNT), according to the formulae provided by Kraemer & Kupfer in 2006. The NNT is the number of persons that have to be treated in order to generate one more positive outcome than in the control group. Subgroup analyses were conducted according to the mixed effect model. In this model, studies within subgroups are pooled with the random effects model, while tests for significant differences between subgroups are conducted with the fixed effects model.

Results
Description of included trials
Seventeen trials met our inclusion criteria, with a total of 3,010 participants (1,538 in the psychological treatment groups, 1,322 in the control groups, and 150 in the alternative treatment groups). Selected characteristics of the included trials are presented in Table I.

Five trials compared a psychological treatment with a care-as-usual control group, while another nine trials used a waiting list control group. The remaining three trials used another type of control group (enhanced routine care, pill placebo, psychological placebo). Seven trials were focused on depressed patients, eight on patients with an anxiety disorder (four on post traumatic stress disorder, two on social phobia, one on panic and one on OCD), while two trials were focused on patients with depression or anxiety. In twelve trials, the presence of the mental disorder was established with a diagnostic interview, while in the remaining five trials patients were included on the basis of a high score on a rating scale.

Of the 22 psychological treatments that were examined in the included trials, 15 could be characterized as cognitive behaviour therapy (CBT) or a strongly related procedure (such as exposure). The remaining seven therapies examined other types of psychotherapy (counselling, interpersontal psychotherapy psychodynamic psychotherapy). Ten of the 22 therapies were group therapies, while the remaining 12 therapies were administered individually. The number of treatment sessions ranged from 1 to 16.

Four trials were conducted each in Brazil and Uganda, two each in Turkey, Pakistan, China and one each in Cambodia, India and Iran. Eight trials were from low-income countries (Pakistan, India, Uganda and Cambodia), three from low-middle income countries (Iran and China) and six from upper-middle income countries (Turkey and Brazil). All trials were published after the year 2000.

Quality assessment
We found that 10 of the 17 trials used an adequate allocation sequence in the randomization process, and 7 trials met criteria for adequate allocation concealment, although true allocation concealment to patients is not possible in trials in which patients are randomized to a treatment or a care-as-usual control group or a waiting list group. In 15 trials the outcome assessors were adequately blinded (blinding of patients was usually not possible), or only self-report measures were used (in which blinding of assessors is not relevant). In 12 trials incomplete outcome data were addressed adequately. We had no indication that in any of the trials selective outcome reporting was a problem, nor did we find other risks of bias in any of the trials. Five of the 17 trials were positive on all six criteria.

Effects of psychological treatments at post-test
We were able to examine the difference between a psychological treatment and a control group in 22 comparisons. The mean effect size was 1.02 (95% CI: 0.76–1.28), which corresponds with an NNT of 1.89. Heterogeneity was very high (F=88.14) and...

statistically significant (p<0.001). The results of these analyses are summarized in Table II. The effect sizes and 95% confidence intervals of the individual contrast groups are plotted in Figure 1.

In our analyses, we included four trials in which two psychological treatments were compared to the same control group. This means that multiple comparisons from this study were included in the same analysis. These multiple comparisons, however, are not independent of each other, which may have resulted in an artificial reduction of heterogeneity and a distortion of the mean effect size. Therefore, we conducted another meta-analysis, in which we included only one comparison per study (Table II). From the study with multiple comparisons we first included only the comparison with the largest effect size. Then we conducted another meta-analysis in which we included only the smallest effect size from the two trials. As can be seen in Table II, these analyses did not indicate that the mean effect size changed considerably, nor did we find indications that heterogeneity was affected by this study.

Both the funnel plot and Duval and Tweedie’s trim and fill procedure pointed and the possibility of significant publication bias. Adjustment for publication bias using Duvall and Tweedie’s trim and fill procedure resulted in a considerably smaller effect size (adjusted effect size: 0.59; 95% CI: 0.29–0.88; number of imputed trials: 7; NNT=2.10).

### Subgroup analyses

We conducted a series of subgroup analyses to examine whether the effect sizes of specific groups differed from each other (Table II). This was especially important because heterogeneity was very high in the main analyses, and subgroup differences were examined. The results of these analyses are presented in Table II. The effect sizes and 95% confidence intervals of the individual contrast groups are plotted in Figure 1. The results of these analyses are summarized in Table II. The effect sizes and 95% confidence intervals of the individual contrast groups are plotted in Figure 1.

Abbreviations: ES: effect size; CI: confidence interval; ITT: intention-to-treat; N comp: Number of comparisons; NNT: numbers-needed-to-be-treated.

a) The p-values in this column indicate whether the Q-statistic is significant (the I² statistics does not include a test of significance).

b) The p-values in this column indicate whether the difference between the effect sizes in the subgroups is significant.

c) All subgroup analyses were conducted with mixed effects analyses,
analyses may give indications for the causes of this heterogeneity.

We found no indication that the effect sizes of trials in which patients were included after a diagnostic interview differed significantly from the effect size of trials in which patients were included on the basis of a high score on a self-rating instrument. We also found no significant difference between trials using individual therapy and those using group therapy, or between trials in which the effect size was based on the intention-to-treat sample and the trials in which that was not done, and between the trials in which all criteria for a low risk of bias were met and the other trials. The income of the country where the study was conducted was also not related to the effect size.

We did, however, find that trials in which CBT was used as treatment resulted in significantly higher effect sizes than trials in which other types of therapy were used. We also found that care-as-usual and waiting list control groups resulted in higher effect sizes than other control groups, although there were only three comparisons in which another type of control group was examined. There was also a trend (p<0.1) indicating that trials in which depressed and anxious patients were both included resulted in a lower effect size than trials aimed at depressed patients or anxious patients, although the “mixed” category included only two trials.

Discussion
Data from this meta-analysis indicate that psychological treatments of depression and anxiety disorders have promise in LAMI countries. We found large effect sizes, which are consistent with effect sizes found in meta-analyses of studies on psychological treatments in high-income countries. This suggests that psychological treatments can be applied successfully in low and middle income countries and may contribute considerably to the reduction of the disease burden of common mental disorders in these countries.

We have to be careful, however, to avoid being over-optimistic about these results. First, we found very high levels of heterogeneity in our analyses, and our subgroup analyses could not give a clear explanation for this. This implies that some studies result in higher and others in lower effect sizes, and we have little understanding of the origins of these differences. This means that psychological treatments are effective in some situations but not in all, and we are not able to predict which of the two will be the case in a specific situation. Second, we found strong indications of publication bias. This suggests that our meta-analysis gives an overestimation of the true effect size of psychological treatments. However, this is also true for studies on psychological treatments conducted in high-income countries. Third, even if psychological treatments are efficacious in LAMI countries, more work is needed to demonstrate their effectiveness in such settings. There may be a number of important barriers to implementing such interventions in resource-constrained contexts.

This study has several limitations that deserve emphasis. First, the number of studies was relatively small. Second, they were conducted in several different countries and cultures, therefore there is limited data from any particular country or culture. Perhaps this can explain in part the high level of heterogeneity in the analyses. Third, several of the included studies had a considerable risk of bias, which may also be responsible for a part of the heterogeneity.

We found indications that cognitive behaviour therapy is more effective than other psychological treatments. It is well-known that cognitive behaviour therapy is an efficacious treatment for many mental disorders, and it may not come as a surprise that we found it to be superior to other therapies. However, in a previous study, we found few indications that cognitive behaviour therapy is more efficacious than other psychotherapies in the treatment of adult depression. Furthermore, in the current meta-analysis, heterogeneity was very high in both subgroups (cognitive behaviour therapies and the other psychotherapies), suggesting that the difference in effect sizes in these two groups were not related to type of therapy, but rather to some other underlying factor which was not examined in our study.

We also found that type of control group was related to the effect size. It is well-known from many studies that waiting list control groups result in much larger effect sizes than care-as-usual control groups, which in turn result in larger effect sizes than placebo control groups (pill placebo or psychological placebo). Apparently, this is not different in psychotherapies conducted in LAMI countries. Studies evaluating treatments aimed at either depression or anxiety revealed significantly higher effect sizes than the two studies looking at both depression and anxiety. This may be an indication of the importance of using specific evidence-based treatments for distinct mental health problems.

Individual and group interventions appear to be equally efficacious in our meta-analysis. This is consistent with literature indicating group interventions to be as efficacious as individual treatments for anxiety and depression. A recent meta-analysis conducted on efficacy studies for depression did find a small difference favouring individual treatments in the short term, but indicated that due to a small numbers of studies with limited quality this should be examined more thoroughly. Individual treatments are generally considered more time-consuming and costly and at first sight not ideal for low-income under-resourced countries. There is relatively limited data on cost-effectiveness of individual versus group treatments, but group treatments may be more cost effective in treating depression, and less cost effective
in treating anxiety disorders. In some low and middle income countries group intervention may be desirable as an extension of traditional sociological structures, but again more effectiveness research is needed in this area.

The result of the included studies indicate that the use of lay counsellors and primary health workers may be helpful in filling the treatment gap in under-resourced contexts. Research studies have used lay counsellors to conduct interventions indicating that psychological interventions carried out by lay counsellors with limited training may be efficacious. Task-shifting at primary health settings may be a way to increase mental health services offered to communities. The mobilization of community resources is proposed in a report by the World Health Organization together with ideas of integrating mental health services into existing primary care services to cope with the under-resourced situation.

**Conclusion**

The common misconception of a lack of psychological mindedness in developing countries is negated by the positive results for psychological treatments in this meta-analysis. The current meta-analysis may therefore help to encourage additional research on psychological treatments in LAMI countries. The World Health Organization has called for an increased investment in mental health research in particularly low and middle income countries. Evidence-based research can reinforce the commitment of policymakers and provide a concrete evidence based programme for scaling up care for mental disorders. There is a need for rigorous effectiveness studies focussing on the feasibility and acceptability of interventions in LAMI countries, as well as on their cost-effectiveness. Evidence of the efficacy and effectiveness of psychological treatments can be used to encourage stakeholders and governments to increase the investment in mental health resources. In this way an evidence base can be created that can inform the scaling-up of interventions for mental disorders in these parts of the world.

The publication dates of randomized controlled trials of psychological interventions for depression and anxiety in LAMI countries indicates that studies in this field are expanding. Most of the studies included in this review were published between 2003 and 2008, and it is hoped that this trend will continue in the years to come. We can expect that in the coming decades a growing number of trials will be conducted to examine the efficacy and effectiveness of psychotherapies in different parts of the world, and where appropriate, the dissemination of psychological and other treatments for depression and anxiety disorders.
