There is no Relationship with Plasma Fatty Acid Levels in New Zealanders with Severe Coronary Artery and Mortality

Jocelyne R Benatar*
Green Lane Cardiovascular Service, Auckland City Hospital, Auckland, New Zealand

Abstract

Background: Objective measures of fatty acid intakes such as tissue levels of fatty acids more accurately reflect dietary intake compared to food frequency questionnaires. This study describes plasma fatty acid levels in New Zealanders with significant coronary artery disease and the relationship with mortality at 7.5 years.

Methods: This is a prospective observational study. Fasting plasma samples were taken in 420 consecutive patients with angiographic diagnosis of severe coronary disease requiring coronary artery bypass surgery. Plasma levels of fatty acids were measured by gas-chromatography mass-spectrometry. Mortality data was obtained by accessing details of the most recent contact with health professionals, review of clinical notes and the National Health Index database and death certificates.

Results: The mean age of participants was 68 (± 10) years and 83% were male. Saturated fats were 46.5 (± 1.2) %, unsaturated fats were 51.8 (± 1.3%) %, trans fatty acids 1.1 (± 0.69) % of total fats. Ruminant transfatty acids made up 67% of total plasma trans fatty acids. Saturated fats and ruminant trans fatty acids levels were not associated with increased total mortality (hazard ratios 0.93 (0.75 to 1.16) p=0.53 and1.4 (0.85 to 1.53) p=0.39 respectively or cardiovascular mortality (hazard ratios 0.93 (0.75 to 1.16) p=0.53 and 0.91 (0.61 to 1.37, p=0.66).

Conclusion: Saturated and trans fatty acid levels in this population are higher than expected from food frequency questionnaires. More than two thirds of transfatty acids are from dairy food and meat. Neither saturated fats nor transfatty acids are associated with increased cardiovascular and total mortality.

Keywords: Trans; Saturated; Fats; Dairy; Mortality; Cardiovascular

Introduction

Evidence suggests that there may be a relationship between certain fatty acids and cardiovascular disease. For example, observational studies suggest that Trans Fatty Acids (TFA) is associated with increased total and cardiovascular mortality [1,2]. However, most TFA in those populations is derived from partially hydrogenated vegetable oil, with little coming from ruminant sources [3-13]. The effects of TFA derived from animal byproducts is less clear with one author suggesting that all TFA regardless of source is associated with increased mortality but others suggesting that ruminant TFA(TFA) have no effect [2,14].

A Cochrane review contends a small, but potentially important, reduction in cardiovascular risk with reduced SFA intake [15]. The postulated effects of SFA on heart heath are thought to depend on the type of SFA. For example, long chain fatty acids are thought to be harmful but medium chain fatty acids are thought to have neutral or beneficial effects. However, the recent meta-analysis by Rajiv Chowdhury and review by Siri-Tano suggests that there is little distinction between the effects of different SFA isomers [16-18].

Meal diaries and food frequency questionnaires have been found to be unreliable to assess dietary intake [19,20] and it is now suggested that objective measurements of dietary intake be more widely used. One such measurement is plasma levels fatty acids which reflect dietary intake for the last 2-3 weeks [21]. In this study, plasma level of all fatty acids including TFA isomers was measured in New Zealand subjects with severe symptomatic coronary artery disease. The relationship between total and cardiovascular mortality at 7½ years and fatty acid levels was described.

Methods

This is a prospective observational study. The primary study endpoint of this study is all-cause and cardiovascular mortality at 7½ years.

Study population and clinical data

Four hundred and twenty two sequential patients with symptomatic severe coronary artery disease diagnosed by angiography were invited to participate in this observational study from August 2004 to September 2006. Ethics approval was obtained. All participants provided written informed consent after the diagnostic coronary angiogram.

Measurement of FA and biomarkers

Fasting blood samples were taken in ethylene-diamine-tetra acetic acid tubes. Plasma was separated and stored at -70°Celsius until analysis. Plasma Phospholipids analysis was performed at the Nutrition and Functional Food Science Laboratory, the University of Adelaide, Australia. Total lipids were extracted with AR Methanol and fatty acid methyl esters formed by transmethylation [22]. Serum phospholipid fatty acid composition was assessed by gas chromatography (Hewlett Packard 6890 Gas Chromatograph with an SGE BPX70 column and a Flame Ionisation Detector). 18:1n-7 (vaccenic acid), 18:1n-9t (elaidic acid), 18:2t (linoleic acid), 16:1t and total TFA were measured.

Levels are expressed as the percentage of the g/100g of the plasma phospholipids acids.

CRP was measured using a high sensitivity assay using the Roche CRPXL immunoturbidimetric method on a Roche Modular analyzer and levels are expressed as (mg/dl). BNP was measured using the Advia Centaur BNP assay (Bayer Diagnostics and levels are expressed as pmol/L. Creatinine was measured using Roche Modular P unit (Roche Diagnostics). Levels are expressed as mmol/l.

Attainment of mortality status

This was obtained initially by reviewing the National Health index database. Patients were deemed alive as of 01 February 2014 if no date of death was listed in the National Health Database and evidence of patient contact was found. Contact was defined as evidence of a face to face visit to the general practitioner, hospital, and laboratory or community pharmacy in the month of February 2014. Contact was determined by checking hospital notes, laboratory results and contacting the general practitioner.

For those who had died, hospital notes, laboratory and radiology tests and death certificates were reviewed, and when not available, information was obtained from the general practitioner.

Clinical definitions

Cardiovascular death was defined as death resulting from an acute myocardial infarction, sudden cardiac death, death due to heart failure, death due to stroke, and death due to other cardiovascular causes [23].

Statistical analysis

Two hundred and fourteen participants was estimated to give 90% power to detect a difference in fatty acid levels between the two groups (alive and dead), with a two-sided 0.05 significance level, if the true difference in fatty acids between groups is 0.02% with a SD of 0.1.

Results are presented as mean and standard deviation for population characteristics and median and Interquartile Range (IQR) for FA levels and biomarkers.

The Mann Whitney U test was conducted to determine differences in SFA and TFA levels between those who died and were still alive and to compare age, C- reactive protein, creatinine, white cell count and BNP between the two groups.

The distribution of ethnicity and gender between the groups was compared with the two-sample Z test. Univariate Cox proportional hazard regression was used to assess the relationships between SFA and TFA with total mortality, CV mortality and non CV mortality. Statistical analyses were performed using the statistical package SAS version 9.3 (SAS Institute, Cary, NC). All p-values resulted from two sided tests and a p-value of <0.05 was considered statistically significant.

Results

Baseline characteristics for the 422 participants included in the study are presented in (Table 1). The mean age was 68 (±10) years and 83% were male. The majority of participants were of European descent (55%), with a smaller proportion Maori (14%), Pacific Islander (6%), South Asian 27 (7%) or other ethnicity 92 (23%). Cardiovascular risk factors included a history of present or past smoking (73%), hypertension (53%) and diabetes treated with pharmacotherapy (27%). The average body mass index was 28 (SD 4.7) kg/m2 and waist circumference 101 (± 12.5) cm. Saturated fats were 46.6 (IQR 45.8 to 47.3) %, unsaturated fats were 51.8 (IQR 50.5 to 53.0) %, TFA 0.84 (IQR 0.67 to 1.20) % in the total cohort. The median plasma levels of the four trans fatty acids measured were as follows: palmitelaidic acid 0.081 (IQR 0.04 to 0.22) %, vaccenic acid 0.45 (IQR 0.35 to 0.72) %, elaidic acid 0.19 (IQR 0.13 to 0.25) % and linolealidic acid 0.09 (IQR 0.07 to 0.11) %.

Average follow up was for 7.5 (± 0.8) years and mortality status and cause of death were available for 421 of the 422 of the cohort. One participant had left New Zealand and no follow-up information was retrievable. All but 13 of the original cohort had coronary artery bypass surgery and in total 95 (22.5%) were dead as of 1st February 2014.

Gender and race did not predict mortality; however, the inverse was true for increased age, creatinine, inflammatory markers (C- reactive protein) and Brain- Natriuretic Peptide (BNP) (Table 2). When multivariate analysis was performed, C- reactive protein was no longer significant (p= 0.06), but age, creatinine and BNP remained significant with p<0.001 for all three.

Table 3 shows association of SFA and TFA with total mortality. Total SFA did not predict total mortality (hazard ratio 0.98 (0.64 to 1.44), p=0.64, or cardiovascular mortality (hazard ratio 0.93 (0.75 to 1.16) p=0.53). No saturated fat isomer was associated with increased mortality. Similarly, total TFA did not predict total mortality (hazard ratio1.14 (0.85 to 1.53) p=0.39) or cardiovascular mortality (hazard ratio 0.91 (0.61 to 1.37, p=0.66). Whilst linolealidic acid was associated with increased total mortality (p=0.023), levels were very low with markedly skewed distribution to the left.

Discussion

SFA and TFA levels in this population are higher that than expected from food frequency questionnaires [24]. The most common fats in this population with significant cardiovascular disease are the long chain fats, palmitic and stearic acid. Ruminant TFA made up 67% of the total TFA in this population whereas in most developed countries industrial TFA is more common [3,5]. The relatively high levels of SFA and TFA may reflect the high intake of dairy food in the New Zealand population. Dairy food is the most significant source of animal fat in the human diet and New Zealanders have a relatively high intake of this [24]. As one of the world’s most significant producers of dairy food this has been strongly promoted as part of healthy diet. The relatively high TFA levels may also be partly explained by the practice of grass feeding cows in New Zealand that increases TFA content in milk [25,26].

TFA is consistently associated with increased mortality in cohorts with higher TFA levels that are mainly derived from partially hydrogenated vegetable fat [2,3,17]. However, TFA levels in this
p<0.05, BNP remained significant (p<0.001), but CRP was no longer significant of follow up. Results are median (IQR) or number (%) as appropriate. When Baseline characteristic of those who were alive or dead at 7.5 years

Table 3: Saturated and trans fatty acid levels in those who were alive or dead at 7.5 years of follow up. Results are expressed as % total fatty acids and are reported as median and interquartile range.

Evidence also suggests that a low fat diet may not be effective at reducing cardiovascular disease, compared to a diet where SFA is substituted with PUFAs [32,33]. In countries that have embraced a low fat diet, there are increased rates of diabetes and obesity, thought to be due to a compensatory increase in the consumption of carbohydrates [34,35].

In this study, creatinine, age and BNP measured at time of diagnosis are associated with increased risk of death after coronary artery bypass surgery. These findings concur with other studies that have found that these risk factors are associated with increased mortality in patients with cardiovascular disease [24-26]. However, the findings that pre-operative BNP predict mortality e after patients have had complete revascularization despite adjustments for the most significant risk factors for post-operative mortality is novel and will need further study [36,37].

The strength of this study is that survival information on all but 1 participant was available, and the cause of death was able to be ascertained on all participants.

The limitations of this study are that information on diet was not collected and only one blood test was collected. Relation between plasma levels of different FA and diet could therefore not be directly assessed. The single blood test excludes evaluation of variation of levels over time. Dietary studies suggest that the majority of the population have a consistent eating pattern, so it is expected that there is a small variation of fatty acid levels within individuals [38]. The study has been undertaken in patients with severe coronary artery disease; it is possible that the fatty acid levels seen in this study do not reflect levels in the general population.

Conclusion

This study suggests that in New Zealanders patients with significant coronary artery disease, total plasma TFA levels are low, and these are mainly derived from meat and dairy. SFA and TFA levels are higher than expected from dietary modeling. These fatty acids are not associated with increased risk of total and cardiovascular mortality.

Acknowledgement

We thank all the patients who participated in the study, the research staff of Green Lane Cardiovascular Research Unit, Auckland City Hospital, the Fatty Acid Lab and The University of Adelaide who assisted in the measuring of fatty acid levels.
