Abstract

Treatment of tendon injuries is a subject of frequent debate in sports medicine and physiotherapy. Achilles and patellar tendinopathy is a common, painful, overuse disorder, and is associated with a failure of the tendon repair process they have a low potential for healing with the usual techniques.

Therefore, new treatments for tendinopathies drawn from the existing literature as well as from their own experience dealing with this condition to deal with this delicate pathology have been developed over recent past decades.

This brief review aims to update recent information on the treatment with the ultrasound-guided EPI® technique and eccentric exercise in Achilles and patellar tendinopathy resulted in a great improvement in function and a rapid return to the previous level of activity.

Keywords: Tendinopathy; EPI® technique; Eccentric exercise therapy

Introduction

The Achilles tendon and patellar tendon are most affected, in both elite and recreational athletes, in sports that heavily load the lower extremities [1]. It is tendons play an essential role in the musculoskeletal system by transferring the tensile loads from muscle to bone so as to enable joint motion and stabilization [2]. Despite this ability to adapt to physiological loads tendinopathies it represents a clinical problem which affects both professional and recreational athletes as well as people involved in repetitive work [3,4]. Tendinopathies overuse represents 30 to 50 % of all sports injuries and result in a significant amount of morbidity and spending health care [5], it is estimated that they could cost the United States health system some 30 billion dollars, annually [6].

The etiology de la Achilles and patellar tendinopathy includes lifestyle, loading pattern, biological variables (genetics, age, sex) as well as different pharmacological agents [7].

Achilles tendinopathy is more prevalent in the lower extremity, with a frequency of 5.9% in sedentary and about 50 % for endurance athletes [8,9]. Patellar tendinopathy is most common involvement in the knee and its prevalence has been reported to be 44.6% in elite volleyball players [10] and 31.9 % in elite basketball players [11] and also represents two thirds of all pathologies of the knee between these two sports [8].

The traditional model of “tendinitis” as an inflammatory process is now obsolete since the appearance of several publications, which have described the pathological process of the tendon as mainly degenerative (tendinosis) [12,13]. This is justified due to the absence of inflammatory cells, the presence of areas of collagen degeneration, myxoid degeneration and an increase in fundamental substance and is associated with a failure of the tendon repair process [12,13].

Achilles and patellar tendinopathy is a clinical diagnosis and typically is based on medical history and clinical findings. Imaging techniques: such as Color Doppler Sonography (CDS) and Magnetic Resonance Imaging (MRI) are valuable tools to confirm the diagnosis and provide guidance for treatment [14].

The tendon injury can occur in the tenotenodinous region, as in the Achilles tendon. However, most of the tendon pathology and pain is located in the osteotenodinous, such as elbow lateral epicondyte, patellar tendon and the medial epicondyte tendons and tendons in the groin [15]. While osteotenodinous and tenotenodinous and are morphologically different region in normal state, the occurrence of extracellular matrix pathology induced cellular changes are indistinguishable [16].

Achilles and patellar tendinopathy this is accompanied by an excessive nociceptive signalling from the tendon, causing pain and restricted mobility [17] he mechanisms behind these structural and neurological changes are not fully understood. A more recent theory ascribes part of the tendinosis changes to an increased production of biochemical agents, such as substance P (SP) [18] and NMDAR1 glutamate receptor [19,20].

Overall tendinopathies are characterized by prolonged, localized pain, associated with physical activity requiring cyclic mechanical stimuli. Patients respond poorly to most conservative treatments, however, a broad spectrum of disorders of the tendon within the concept of tendinopathy that share some common characteristics (paratendinitis, tendinitis, tendon overuse injuries, spontaneous tendon rupture, calcifying tendinitis) or gaps, often converge in the same tendon (Figure 1). In this sense, there is no single etiology and pathogenesis that can explain all these processes [15].

Treatment options have changed over the last decade in parallel to...
Ultrasound-guided EPI® technique

In recent years, the intratissue percutaneous electrolysis (EPI®) technique has become more relevant in the scientific literature [31-33] given the good results yielded in the treatment of degenerative tendinopathy in comparison to other previous conservative treatments.

This technique, created by Sánchez-Ibáñez JM [34,35] and who have over 15 years experience in its use, uses a flow of cathodic current directed exclusively to the area of degenerated tendon through an ultrasound guided needle that brings about an organic reaction that leads to rapid regeneration of the degenerated tendon.

The application of EPI® technique produces a non-thermal electrochemical reaction centered on degenerated tissue (tendinosis). This leads to a controlled local inflammatory reaction that leads to the regeneration of damaged tissue [33,36].

The EPI® technique (Figure 2) achieves a very localized organic reaction in the clinical focus by using a specially designed EPI® device for this purpose (EPI Advanced Medicine®, Barcelona, Spain. EPI® technique videos online: www.epiadvanced.com), which leads to the rapid regeneration of degenerated tissue. This leads to the production of new immature collagen fibers that become mature by means of eccentric stimulus [32], thereby obtaining good results in the short and long term.

Eccentric exercise therapy

Eccentric exercise therapy has shown to cause an upregulation of Insulin-like Growth Factor (IGF-I). This upregulation of IGF-I is associated with cellular proliferation and matrix remodelling within the tendon [23].

Programs of eccentric exercise have been proposed as a key element in strength training in rehabilitation because they can supposedly counteract the response of defective healing that apparently underlies tendinopathy by promoting the creation of collagen fibers within the tendon [24,25]. The literature places increasing emphasis on the importance of a proper choice of the load used [26].

The continuum model in tendinopathy (reactive tendinopathy, tendon dysrepair and degenerative tendinopathy) provides a reasoned basis for believing that the protocol to be performed depends on the current clinical presentation [15]. The protocol proposed by Alfredson et al. is generally used [24] it consists of three sets of 15 repetitions, performed twice a day, seven days a week for 12 weeks.

Ohberg et al. [27] examined tendon structure by grey-scale ultrasound in 26 tendons with Achilles tendinosis, which had been treated with eccentric exercise. Remarkably, after a mean follow up of 3.8 years, 19 of 26 tendons had a more normalised structure, as gauged by their thickness and by the reduction of hypoechoic areas.

Visnes et al. [28] suggested that eccentric training had a positive effect on patellar tendinopathy and recommended that athletes suspend sports activity during rehabilitation.

The gradual progression from eccentric to concentric followed by a faster loading can benefit patients with Achilles tendinopathy can not start with a program proposed by eccentric Alfredson et al [24] due to pain or weakness of the sural triceps muscle [29].

Isoinertial eccentric training (YoYoTechnology AB, Stockholm, Sweden) resulted in an improvement of muscle function and reduced pain in patients with patellar tendinopathy [30]. The combination of EPI® technique and isoinertial eccentric exercise offers good results in the treatment patellar tendinopathy [31].

long-term in terms of pain and function.

In recent studies with human tendon injury, there has been a disproportionate expression of certain cytokines and matrix metalloproteinase (MMPs), prostaglandin E2 (PGE2), interleukin -6 (IL-6) and interleukin -1b (IL-1b) [37,38]. IL-1b in turn increases the production of matrix metalloproteinase -1 (MMP-1), matrix metalloproteinase -3 (MMP-3) and prostaglandin E2 (PGE-2) [39].

A recent experimental study [33] showed that with the use of ultrasound-guided EPI technique in patellar tendinopathy increase of anti-inflammatory proteins, like peroxisome proliferator-activated receptor gamma (PPAR-y). These proteins play a key role in the inhibition of expression of proinflammatory molecules secreted by macrophages, such as tumor necrosis factor alpha (TNF-α), IL-6 and IL-1β, thus producing in the treated tissue a highly beneficial molecular response during degenerative tendinopathy. This, in turn, results in an increase of the expression of vascular endothelial growth factor (VEGF) and vascular endothelial growth factor receptor 2 (VEGFR-2), mediators responsible for angiogenesis anti-inflammatory response. The EPI technique makes for the activation of molecular and cellular mechanisms of the tendon responsible for phagocytosis and the regeneration of degenerated tissue [33,36].

In recent research [31] to evaluate the therapeutic effects EPI technique and eccentric exercise on the patellar tendinopathy. The primary outcome measure was knee function using the Victorian Institute of Sport Assessment–Patella (VISA-P) score, a specific validated questionnaire to quantify pain and knee function and ability to play sport in patients with patellar tendinopathy [40,41]. The VISA-P score ranged from a maximum of 100 in asymptomatic patients to the theoretical minimum of 0. The authors of the score suggested that a score between 80 and 100 points might be considered as the optimal outcome category. Functional evaluation was further assessed with Blazina’s classification [42]. This classification categorizes the symptomatic patients as in phase I (pain only after activity), phase II (discomfort during activity), phase III (pain during activity that interferes with participation) and phase IV (complete tendon disruption). The Tegner score was also used to assess the influence of the treatment in terms of restoring the previous sports activity level. All the written questionnaires were personally filled out by all patient before treatment, at the end of the treatment (at 3-month) and at the 2-year follow-up. The questionnaires corresponding to the 5 and 10 year follow-up evaluations were all filled out through a telephone interview. Patient satisfaction was measured according to the Roles and Maudsley score [43]. In this score, patients are classified as Excellent (no pain, full movement and full activity), Good (occasional discomfort, full movement and full activity), Fair (some discomfort after prolonged activity) or Poor (pain limiting activities). The results documented were good and stable with the VISA-P score, Tegner scores and Roles and Maudsley score, and terms of clinical and functional improvement in patellar tendinopathy and providing a follow-up of 10 year.

In recent research [44] to evaluate the therapeutic effects EPI technique and eccentric exercises on the Achilles tendinopathy. A prospective study of 39 patients with Achilles tendinopathy was carried out. The patients were evaluated using the Victoria Institute of Sports Assessment - Achilles (VISA-A) score and the Foot and Ankle Disability Index for Sport scale (FADI); at the beginning of the study and after being monitored for 3 months. At the beginning of the study, the VISA-A score was an average of 47 ± 19.8 (mean ± SD) and after being monitored for 3 month the score was an average of 90.8 ± 5.5 (mean ± SD), showing statistically significant differences (p<0.001). The results of the FADI showed that the average score at the beginning was 64.5 ± 26.9 (mean ± SD) and after 3 months it was 123 ± 1.5 (mean ± SD). Statistically significant differences were identified (p<0.001). The use of the EPI technique in combination with eccentric exercise in Achilles tendinopathy has shown evidence of a significant improvement in terms of pain and function. Not many sessions are required and the treatment time is short. The procedure has proven to be safe.

**Discussion**

Treatment of Achilles and patellar tendinopathy is a subject of frequent debate in sports medicine and physiotherapy. Multiple techniques have been described for their treatment and although some of them [31,45-48].

To date, there is no consensus on the optimal treatment of Achilles and patellar tendinopathy. It has been suggested that the incomplete understanding of the underlying mechanisms (etioloogy of the condition) limits the ability to develop effective treatment strategies [49].

Doubs have mainly centered on the fact that there are few controlled prospective studies that analyze all aspects of tendinosis, and few studies that investigate the early stages of these processes and their healing mechanisms. The exact mechanism by which tendinopathy develops in humans remains the target of numerous investigations. A variety of degenerative characteristics associated tendinopathies, including accumulation glycosaminoglycan (GAG), calcification and lipid accumulation nerve damage and hyperinnervation, is one of the theories whose publications are scarce, despite its special interest in explaining the possible pathophysiological mechanisms of pain in tendinopathy [50].

In several studies it has been shown that there is a correlation between tendinopathy and hyperinnervation, citing that the production of Nerve Growth Factor (NGF) and the corresponding hyperinnervation could be induced by repetitive ischemic crisis in osteoedentinous union [51,52]. This growth of nerve fibers, which causes chronic pain, could be part of a process of abnormal tissue repair, preceded by repetitive microtrauma [53].

Despite its prevalence, the precise pathogenic mechanisms of tendinopathy are not clear and, as a result, current treatments of tendinopathies are largely empirical and not always efficient [15,54]. The continuum model of tendon pathology was proposed to provide a model for the staging of tendon pathology and to assist clinicians in managing this often complex condition. The model presents clinical, histological and imaging evidence for the progression of tendon...
pathology as a three-stage continuum: reactive tendinopathy, tendon disrepair and degenerative tendinopathy [15].

One of the clinical effects that eccentric exercises might have in tendinopathy is in pain modulation due to changes in glutamate content or in the central nervous system with increased activation of inhibitory neurons and cortical reorganization [48,55]. There is little evidence that isolated eccentric exercise reduces pain in tendinopathy compared with concentric exercise [56].

It is considered that hypoxia could be responsible for neovascularization in tendinopathies, capillary flow and post-capillary pressure decreased following 12 weeks of eccentric loading [57].

In the treatment of tendinopathy, there is conflicting evidence that eccentric exercises are superior to other load programs [56]. Eccentric work on an inclined plane did not improve functional outcomes when it was done during a competitive season in volleyball [58]. In another study, continuous sporting activity did not compromise clinical outcomes at 12 months, as long as the sport was introduced incrementally ensuring minimal pain during and after loading [59]. Eccentric decline squat training and heavy slow resistance training showed good long-term clinical results, and heavy slow resistance training also resulted in advantages in pathological improvement and increased collagen turnover [60].

Some authors have demonstrated better results with eccentric exercise on corporeal tendinopathies in comparison with enthesopathies [22].

On the other hand, maximal eccentric loading may be best for some groups of patients and permit adaptive changes in the tendon [30]. Despite the fact that the eccentric muscle workout has become the dominant conservative strategy in treating Achilles and patellar tendinopathy, up to 45% of patients do not respond to this treatment [61].

A recent study suggests that sedentary subjects with Achilles tendinopathy may show less promising results with eccentric exercise therapy compared to athletic subjects [62].

Despite some good results reported with eccentric programmes [61,63], it is still unclear as to the more effective exercise protocol, its frequency, load and dosage.

Despite over 15 years of experience in the use of the EPI® technique and its widespread deployment in sporting clubs around the world, this technique has grown in relative to scientific dissemination in recent years [31-33].

The EPI® technique is contraindicated mainly in patients with tumors, articular or systemic infection and bleeding disorders [34].

An experimental study showed that after application of the degenerated tendon EPI® technique, an increase in anti-inflammatory proteins, like PPAR-γ has been observed after treatment with the EPI® technique. These proteins play a key role in the inhibition of expression of proinflammatory molecules secreted by macrophages, such as TNF-α, IL-6 and IL-1β [64] thus producing in the treated tissue a highly beneficial molecular response during tendinopathy. This, in turn, results in an increase of the expression of VEGF and VEGFR-2, mediators responsible for angiogenesis anti-inflammatory response [65,66].

In another recent study by Sánchez-Ibáñez and co-workers [31] reported that treatment with the ultrasound-guided EPI® technique and eccentric exercises in patellar tendinopathy resulted in a great improvement in knee function and a rapid return to the previous level of activity after few sessions. The limitations of this study are the absence of a control group.

References to the use of the EPI® technique in combination with eccentric exercise can be found in the literature. In those cases the EPI® technique focuses on biological tissue recovery, leaving the functional recovery of tissue biomechanics to eccentric exercise [31].

Conclusions

Achilles and patellar tendinopathy is a condition that causes many patients significant pain and disability. Currently, the aetiology of tendinopathy is still unclear, it is multifactorial, and influenced by intrinsic and extrinsic factors. Tendinopathy often becomes chronic because the exact pathogenesis remains largely unknown. Physicians and physiotherapist have a variety of therapeutic options available to treat tendinopathies but, in each case, there is a lack of evidence supporting their use as the gold standard treatment.

The combination of EPI® technique and eccentric exercise offers good results in terms of clinical and functional improvement in Achilles and patellar tendinopathy with low morbidity in a half study period.
